The various streptococcal species have many biologic similarities and differences. The genus name suggests a "twisted chain," which describes the microscopic appearance of many species, especially when grown in broth culture. The pneumococci are commonly described (and were formerly named) as diplococci because of their propensity to occur in pairs, but they are often indistinguishable from other streptococci in blood cultures. All the streptococci have a tough cell wall composed of cross-linked peptidoglycans. Most have a polysaccharide group antigen associated with the cell wall, and some have teichoic acids as major or additional components. Pneumococci exhibit prototypic bacterial polysaccharide capsules. The group A streptococci, in contrast, have the M proteins on their exterior surface, but these appear to play a similar role in helping the organisms resist phagocytosis. The group B streptococci, like pneumococci, have polysaccharide capsules as their major surface antigens. Pneumococci, however, also have autolytic enzymes that break down cell walls in late growth phases, releasing DNA and other intracellular components. Intact pneumococci also take up genetic material and are thus auto-transformable, a characteristic that appears to have facilitated the spread of antibiotic resistance within the species. With few exceptions, streptococci are aerobic and facultatively anaerobic. They are cytochrome-negative, catalase-negative, and ferment sugars mainly to lactic acid but not to gas. All streptococci secrete enzymes extracellularly, but those of group A have been studied most extensively.

4.1. Cellular Antigens and Enzymes

4.1.1. Group A Streptococcal Cellular Antigens and Enzymes. The major components of group A streptococci are the cellular antigens and the extracellular enzymes listed in Table 5. M proteins, noted above and listed in Table 3, are important virulence factors of group A streptococci, contributing to the organism's resistance to phagocytosis in the absence of type-specific antibody.[73] M proteins bind host proteins, especially fibrinogen, as a ploy to evade host defense mechanisms. Although immunity appears to be lifelong, most humans are usually infected by only a few different types and remain susceptible to the other types. Thus, repeated episodes of streptococcal infection may be due to different types rather than to a failure of host response. Certain M types, especially M1 and M3, have been associated with more severe forms of disease, and some are more common in pyoderma and acute glomerulonephritis[4,36] (see Table 3). Others have historically been associated with acute rheumatic fever and are referred to as "rheumatogenic" types. Although rheumatogenicity is not determined by M type alone, evidence for the cross-reactivity of certain M proteins with heart and brain tissue strongly suggests autoimmune mechanisms for the etiology of acute rheumatic fever and Sydenham's chorea.[74,75]

The group A cell wall carbohydrate is a polymer of rhamnose with *N*-acetylglucosamine side chains. Humans normally make antibodies to this antigen but the role of antibodies has been controversial. There is now evidence that this antigen may play a role in sequelae of streptococcal infections by inducing antibodies cross-reactive with cytokeratin.[75] This could provide an explanation for the joint and skin manifestation of acute rheumatic fever and of guttate psoriasis. Vaccinating mice with group A carbohydrate cross-linked to tetanus toxoid appears to induce antibodies that are protective against challenge with group A streptococci.[76]

Hyaluronic acid capsules are produced by some (especially M18) strains, giving colonies a large highly mucoid appearance. This capsule material is indistinguishable from the ground substance of mammalian connective tissue and is not immunogenic. Its effect on virulence in mice is small, although similar capsules may occur on group C streptococci and have greater virulence than unencapsulated strains. Nevertheless, mucoid group A strains have been associated with severe disease in humans and with rheumatic fever.[36,74] Furthermore, the near-disappearance of acute rheumatic fever in the United States may be correlated with the replacement of rheumatogenic M types by nonrheumatogenic types in cases of pharyngitis.[77]

Lipoteichoic acids are composed of polyglycerophosphate attached to lipids. These surface molecules are directly involved in attachment of organisms to host epithelia and are of importance in the initiation of infection.[78] Other cellular components are less well defined in terms of their role in disease. As in other gram-positive bacteria, there is a rigid

cell wall structure made from polymers of alternating glucosamine and muramic acid units cross-linked by peptide side chains. This serves to stabilize the organisms against outside osmotic changes. The peptidoglycan components are highly inflammatory and may play a role in inciting nonspecific host responses. The T proteins, noted above, occur in families that may be shared by a number of M types. The serum opacity factor proteins are coexpressed with specific M types and are not shared among M types.[34] The R antigen is an antigenic surface protein that occurs in strains of various types but appears to play no role in virulence or protection. Like groups C and G streptococci, group A and other streptococci also have antibody-binding proteins that bind antibodies nonspecifically via the Fc fragment, presumably to help the organism avoid specific, complement-fixing, antibody binding.[79]

Group A streptococci secrete various substances into the surrounding milieu that may contribute to the pathogenic process. There are two well-described hemolysins capable of lysing red blood cells and injuring other cell membranes and subcellular organelles.[80] Streptolysin O is the antigenic, oxygen-labile hemolysin used in the ASO test. Streptolysin O is a pore-forming toxin that facilitates the entry of NADase and presumably other toxins into cells.[81] Streptolysin S is nonantigenic, oxygen stable, and is responsible for β-hemolysis at the surface of cultures grown on blood agar under aerobic conditions. This hemolysin acts as an epithelial cell toxin and also impairs phagocytic clearance of the organisms.[82]

Deoxyribonucleases (DNases) are elaborated by groups A, B, C, and G streptococci. DNase B is the most common and most immunogenic of the group A DNases and is the basis of the antibody test of the same name. It is thought that these enzymes along with hyaluronidase and streptokinase combine to produce the thin pus seen in streptococcal infections, in contrast to the thick pus often associated with infections due to other pyogenic bacteria.[1] The pathogenic role of DNases now appears to be aid in evasion of innate host defense mechanisms.[83]

Streptococcal hyaluronidases (produced by groups A and C) are capable of hydrolyzing the hyaluronic acid of group A capsules and of mammalian connective tissue. Although formerly called "spreading factor," its biologic role remains uncertain with regard either to cell metabolism or to the production of disease. It appears that hyaluronidase does facilitate spread of large molecules but not bacteria in the area of infection, but its major role may be to enable the organism to utilize hyaluronic acid as a carbon source.[84]

The streptokinases are antigenic proteins that convert plasminogen to plasmin, which in turn lyses fibrin clots. Group A streptococci produce either streptokinase A, the most common, or streptokinase B. An antibody test based on the former antigen is sometimes employed in the clinical assessment of group A disease. A distinctive low-molecular-weight streptokinase, called "nephritis strain-associated protein," has also been identified from group A streptococci recovered from patients with acute nephritis.[85]

Nicotinamide adenine dinucleotidase (NADase; also called diphosphopyridine nucleotidase, DPNase) is produced by streptococci of groups A, C, and G. Anti-NADase antibodies are produced by the majority of patients recovering from group A streptococcal pharyngitis, but responses are poor following skin infections. NADase is toxic to leukocytes but requires pores formed by streptolysin O in order to enter cells and enhances the virulence of the organisms in vivo.[81] Recent studies have found NADase production in all strains of group A streptococci isolated from invasive cases and have demonstrated that the current expression of NADase in M-1 strains correlated with the temporal emergence of M-1 strains associated with invasive disease around 1985.[86]

Several proteinases of group A streptococci have been carefully studied and shown to exert pathologic effects in vitro and in vivo. A specialized peptidase has been described that diminishes chemotactic activity by inactivation of the C5a complement component. *Streptococcus pyogenes* exotoxin B (SpeB) is a cysteine protease that cleaves the hinge region of human IgG and has other immunomodulating properties.[87]

Streptococcal pyrogenic exotoxins (SPEs) are the erythrogenic toxins responsible for the characteristic rash of scarlet fever. These enzymes have been implicated as factors in streptococcal toxic shock, where they appear to be potent activators of tumor necrosis factor (TNF) and other cytokines.[4,88] There are three classic antigenically distinct toxins, designated SPE A, B, and C. All group A streptococci carry a gene *(speB)* that codes for SPE B, but it is not understood why some strains are stronger producers of the toxin than others. SPE A and SPE C are encoded by lysogenic bacteriophages, and only those strains infected by the phages are capable of producing toxin. Humans make antibodies to SPE A, B, and C, which appear to confer toxin-specific immunity to scarlet fever. It is possible to have scarlet fever more than once, due to different toxins. A large family of SPEs (so far SPE D–M) have now been identified with various pyrogenic, mitogenic, and superantigen properties.[89] The classic determination of susceptibility to scarlet fever is the Dick test.[1] Seldom used today, it is based on the observation that patients with antibody to a specific toxin show no response to a small intradermal injection of that toxin (negative Dick test). Susceptible individuals, who have no

antibody to neutralize the toxin, develop inflammation at the injection site within 24 h (positive Dick test). SPE A shares structural and physiologic similarities with TSST-1, one of the toxins associated with staphylococcal toxic shock syndrome (see also Section 7.1).

4.1.2. Group B Streptococcal Cellular Antigens and Enzymes. The group B streptococci differ from group A in that their virulence may be accounted principally by capsular polysaccharides rather than proteins. The capsular types, noted in Section 3.4.1 and in Table 4, are antigenically distinct by virtue of variations in linkages of the same essential sugars. A key feature is that all have terminal *N*-acetylneuraminic acid (sialic acid) residues that are major immunodeterminants. The capsules are antiphagocytic and require specific antibody for efficient opsonization. The quantity of sialic acid-containing antigen appears to be directly related to size and density of the capsule and to virulence in animal models.[90,91] The capsular material itself appears to inhibit the activation and chemotactic functions of neutrophils.[92] Many group B strains are also capable of binding fibrinogen to their surface in a manner that competes with the nonspecific binding of C3 complement.[87,92]

The group B antigen is a complex glucitol-containing polysaccharide associated with the peptidoglycan cell wall. Antibodies to the group B antigen are generally not protective, presumably because it is covered by capsular material. A human monoclonal IgM antibody to the group B antigen has been described that opsonizes strains of all serotypes,[93] but the large amount of antibody required appears to make impractical as an adjunctive therapeutic agent.

The major surface structures and protein antigen of group B streptococci have been reviewed by Lindahl and colleagues.[44] The major protein to be studied was the c protein, which occurs on all type Ib and some type II and III strains. Antibodies to this antigen are protective,[94] but common variants of the protein apparently confer resistance to intracellular killing by neutrophils. An important property of the beta c protein may be its ability to nonspecifically bind human IgA.[92] The alpha c protein is involved with adherence to epithelial cells via a glycosaminoglycan-binding region and mediates entry in host cells.[95] The R and X antigens are rarely seen in human isolates and probably play no role in protection or disease. Also present are lipoteichoic acids (LTA) that resemble the lipopolysaccharides (LPS) of gram-negative bacteria and engage the Toll-like receptors (TLR-2) of the innate defense system.[96]

The group B streptococci elaborate a number of extracellular enzymes, including hemolysins, CAMP factor, DNases, and "neuraminidase." Pritchard et al. have shown that the enzyme thought for many years to be a "neuraminidase" is in fact a hyaluronic acid lyase that has a unique mechanism of action quite unlike that of hyaluronidases produced by group A streptococci or pneumococci.[97] Group B streptococci have several hemolysins, one of which has been identified as cytotoxic for mammalian cells in vitro and inhibited by phospholipids common to pulmonary surfactants.[80] The CAMP factor potentiates the activity of staphylococcal sphingomyelinase in vitro but is not essential for systemic virulence.[98] Like group A, group B streptococci elaborate a proteinase that decreases chemotactic activity by specifically cleaving complement C5a.[44,99] A pyrogenic exotoxin has also been identified from strains associated with a group B streptococcal toxic shock-like syndrome in infants.[100]

4.1.3. Pneumococcal Cellular Antigens and Enzymes. *Streptococcus pneumoniae* is the paradigm of encapsulated bacteria. Its polysaccharide capsules are essential to virulence and antibodies against the capsule are the major specific defense against infection. The 90 recognized type-specific polysaccharides vary in composition, including linear polymers, branched chains, and teichoic acid-like antigens. The most frequently occurring types have been selected for inclusion in the presently licensed vaccines.[101]

The C-polysaccharide corresponds to the group carbohydrates of other streptococci but differs significantly in structure. Its major antigenic determinant is phosphocholine, linked to ribitol phosphate, galactosamine, and other sugars. Although humans make "natural" antibodies to this antigen, opsonization of pneumococci (and presumably protection) is almost entirely dependent upon anticapsular antibodies.[102] The Forssman antigen is a membrane teichoic acid similar to C-polysaccharide but linked to a lipid, forming what is essentially the lipoteichoic acid of the pneumococcus.

Pneumococcal surface protein A (PspA) has been identified on essentially all important clinical isolates and appears to play an important role in virulence. Humans including young infants make antibodies to PspA and to various other surface proteins, suggesting their use in a vaccine.[103] Enzymes produced by pneumococci include pneumolysin, amidase (the autolytic enzyme that breaks down cell wall material), neuraminidases, and IgA proteases. Pneumolysin is a pore-forming toxin that bears extensive amino acid sequence homology to streptolysin O and to the theta-toxin of *Clostridium perfringens.* It is highly toxic to pulmonary epithelial cells and may be important to the pathogenesis of pneumonia.[101]

4.1.4. Components of Other Streptococci. Other pyogenic streptococci share many characteristics noted above. All have rigid peptidoglycan cell walls, with various

distinctive or group antigens, and usually with some form of lipoteichoic acid. Group C streptococci may have hyaluronic acid capsules like those of group A. Group G streptococci may have the type 12 M protein of group A or similar surface proteins, as well as antibody-binding proteins. The group C streptococci from human, equine, and porcine sources produce species-specific streptokinases that are otherwise similar to those of group A.[104] A streptokinase derived from group C has been used clinically in attempts to clear clotted intravascular catheters, to lyse pleural adhesions in patients with lung infections, and to help remove clots in patients with coronary artery occlusions. Group G streptococci also produce streptokinases. We have described a patient with nephritis following infection with a group G strain that had a low-molecular-weight enzyme similar to the nephritis strain-associated protein of group A.[105]

The enteric and oral streptococci are usually unencapsulated. Some in the *S. anginosis* (*milleri*) group appear to have capsules more often when found in abscesses, and the capsules play a role in protection from phagocytosis.[106] Few toxins or noxious enzymes have been described among the enteric and oral streptococci, but this may be from lack of concerted investigation. Members of the *S. anginosis* group have, at the least, hyaluronidase, deoxyribonuclease, and various proteinases.[24,106] For many of the less virulent streptococci, the inflammatory response to infection probably relates more to the properties of the cell wall breakdown products than to specific enzymes or toxins. Characteristics that enable them to cause disease often relate to their ability to adhere to host tissues, such as tooth enamel, heart valves or prostheses, or to intravascular catheters. *Streptococcus mutans,* for example, adheres to the pellicle coating the tooth surface by specific protein receptors called antigen I/II; adhesion is further facilitated by the presence of sucrose. *Streptococcus mutans* also produce extracellular proteases that are capable of breaking down cemental collagens and other host substrates. Caries occur when the secretion of acids demineralizes the enamel and organisms adhere to and invade the tooth surface. *Streptococcus mutans* also produce mutacins, bacteriocin-like antibiotic peptides, that help protect their ecological niche in dental biofilm.[9,107] Enterococci and *S. anginosis* group streptococci are frequently found in mixed infections, especially in association with anaerobic bacteria, suggesting that additional factors are required for them to cause disease. Enterococci produce several pheromones that are chemotactic for neutrophils and may contribute to the inflammation associated with infection. *Enterococcus faecalis* also produces a plasmid-encoded hemolysin. Because enterococci are frequently resistant to common antibiotics, serious enterococcal disease also occurs as superinfection in patients receiving broad-spectrum antibiotics that may disturb the normal ecology of this usually benign organism.[12]

4.2. Antibiotic Susceptibility

The streptococci are generally quite susceptible to penicillin, including most oral and *S. anginosis* group streptococci. Exceptions include some pneumococci and group D streptococci, and the enterococci. Although streptococci are generally resistant to aminoglycosides, gentamicin is sometimes used for its synergistic effect in combination with a penicillin, particularly in patients with endocarditis due to viridans streptococci and enterococci.[108] Chloramphenicol has occasionally been used in penicillin-allergic patients, but other drugs, including erythromycin, clarithromycin, and clindamycin, are considered to be superior for most streptococcal species.

Groups A and B streptococci have never developed resistance to penicillins, probably because they are not naturally transformable, as are pneumococci and enterococci. They are somewhat less sensitive to vancomycin and cephalosporins, moderately resistant to chloramphenicol, and fairly resistant to aminoglycosides, sulfonamides, and tetracycline. Group B strains have shown some tolerance to penicillin, but the clinical significance of such observations is unknown. Tolerance to penicillin has also been suggested as one mechanism by which group A streptococci persist after treatment of pharyngitis. But although there may be a modest increase in efficacy of cephalosporins compared to penicillin, the explanation appears to be the more efficient eradication of the carrier state in patients whose pharyngitis was actually due to viral causes.[109,110] Another mechanism is thought to be the protection of susceptible streptococci by the production of β-lactamases by other bacteria in the pharynx or tonsils,[111] although this concept has been disputed.[112] Another explanation is that the streptococci penetrate the epithelial cells where they may persist even in the presence of extracellular penicillin.[113] Resistance to erythromycin occurs in about 5% of group A strains in the United States and most other parts of the world. However, local rates from 25 to 50% have been reported in Korea, Italy, and Pittsburgh, Pennsylvania. Resistance rates parallel antibiotic use and may be reduced by improving prescribing practices.[114,115]

Penicillin resistance in pneumococci has emerged slowly over the past two decades and has now become a frequent and serious problem worldwide. Most of these strains have intermediate susceptibility (MIC 0.1–1.0 μg/ml) but highly resistant strains (MIC >1.0 μg/ml), initially reported from South Africa and Spain, have now spread throughout Europe and North America. The widespread use of fluoroquinolones,

macrolides, and azithromycin has led to increased resistance to those drugs in many areas.[116] Of considerable concern is the recent emergence of strains with very high resistance to penicillin and of multiresistant serotype 19A strains, because they are not included in the 7-valent conjugate vaccine (which contains type 19F).[117]

Although group B streptococci remain sensitive to penicillin, some strains can be penicillin tolerant, which has been speculated as a cause of treatment failure in cases of invasive disease.[118] Another problem is the increasing resistance to erythromycin and clindamycin, which are used as alternatives to penicillin in antibiotic prophylaxis for allergic women.[27] Resistance mechanisms to macrolides and clindamycin have been identified as methylase genes erm(B) and erm(TR) and efflux genes mef(E) and mef(A).[119]

Enterococci are moderately resistant to penicillins alone, because of the intrinsic properties of their penicillin-binding proteins. *Enterococcus* strains with resistance to β-lactam antibiotics and high-level resistance to aminoglycosides began to appear in the 1980s. Some strains of *E. faecalis* have also acquired β-lactamases as a mechanism of resistance.[120] Infections are usually treated with penicillin or ampicillin plus an aminoglycoside, which exert a synergistic effect against the organisms. Vancomycin-resistant enterococci (VRE), especially *E. faecalis,* made their appearance in the late 1980s and have been an increasing problem ever since.[57,121] Vancomycin acts by binding to the D-alanine–D-alanine on the end of cell wall muramic acid precursors. Resistance conferred by a plasmid or transposon carrying the *vanA* or similar gene, allows the organism to generate muramic acid precursors with peptides ending in D-alanine–D-lactate, to which the vancomycin has low affinity. VRE present difficult therapeutic challenges, because there are few alternatives to vancomycin.[12,57] Most VRE are *E. faecium*, which is sensitive to quinupristin–dalfopristin, but *E. faecalis* is resistant. Linezolid is effective against both species, but as more linezolid is being used, resistance has started to appear.[58]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

Group A streptococcal pharyngitis is one of the most common acute bacterial infections. The frequency of this disease, especially as manifested by scarlet fever, has declined dramatically since the beginning of the century, as illustrated in Figure 1.[1] The severity of the disease, reflected by mortality rates, declined concomitantly. This trend began long before the advent of antibiotics, suggesting a decrease in virulence or an increase in host resistance, or both. In the 1940s penicillin became widely available, and deaths attributed to scarlet fever and puerperal sepsis, the two most common lethal forms of group A streptococcal disease, became a rarity. The number of reported cases of streptococcal sore throat increased during the 1950s and 1960s, probably because of increased physician awareness of its relation to rheumatic fever, greater use of throat cultures, and the availability of antibiotics for treatment and prevention. Since the 1960s only one population-based study of streptococcal sore throat in an industrialized country has been published, a prospective study of 202 Australian families with at least one child in the 3- to 12-year age group.[122] The incidence of culture-positive cases was 13 per 100 child-years and was eight per 100 child-years for serologically confirmed group A streptococcal infection. This was similar to previous studies in suburban populations, but rates were about half that seen in crowded lower socioeconomic settings and lower still that in present day indigenous populations.[122]

Figure 2 shows the number of positive throat cultures and number of cases of acute rheumatic fever and acute glomerulonephritis in private pediatric practices participating in surveillance studies in Rochester, New York, over a 20-year period. These data were compiled and kindly supplied by Caroline Breese Hall, University of Rochester. Of approximately 23,000 throat cultures done annually, 18–25% were positive for group A streptococci in this relatively stable population. Meanwhile, the number of cases of acute glomerulonephritis declined from nearly 40 in 1967 to an average of one case per year from 1981 to 1988. Confirmed cases of acute rheumatic fever dropped from 20 to 28 per year to a very few from 1975 to 1985 and have continued to be very low. For example in Baltimore, between 1960 and 1964, the incidence of rheumatic fever was 26 per 100,000 among 5- to 19-year olds. By 1980 the rates had fallen to 0.2–0.8 per 100,000 nationwide among whites, but with rates several times higher among other ethnic groups. Beginning in the mid-1980s, an increase in new rheumatic fever cases was seen in Utah, Pennsylvania, Ohio, New York, and other areas. Disease incidence peaked in Utah in 1985 with 18 per 100,000 population age adjusted for 5- to 17-year olds,[3] and rates peaked again in 1998 and have subsequently declined.[123] Of particular interest was the observation that throughout this period incidence rates were essentially unchanged in Hawaii and New Zealand, where the disease is especially prevalent among Polynesian children. The explanation may be the local prevalence of certain rheumatogenic M protein types many of which were characteristically mucoid, whereas in other areas of the United States these have been largely replaced by nonrheumatogenic types.[77,123]

There has not been a similar decline in rheumatic heart disease in the developing world.[23] In a program begun in 1984 the WHO Cardiovascular Disease Unit surveyed 16 developing countries and found rates averaging 220 cases per 100,000 childhood population. Highest rates were in Africa and the eastern Mediterranean, lowest rates were in Southeast Asia and the Western Pacific. More recent data have found that prevalence rates of clinically diagnosed rheumatic heart disease have not changed in Cambodia in 2001–2002 (220/100,000) and Mozambique in 2005 (230/100,000). However, echocardiographic screening for mitral or aortic regurgitation revealed that 10 times as many children were affected.[124] The major problem in the developing world is establishing and maintaining effective primary and secondary prevention programs.[125] This principle applies as well to developed areas, such as Miami, Florida, where underprivileged inner-city children have attack rates of 15/100,000, compared to 0.7/100,000 for suburban middle-class children.[126]

Deaths from acute rheumatic fever are uncommon today. In developed countries deaths associated with chronic rheumatic heart disease continue to occur in persons who had acute rheumatic fever in childhood and develop severe mitral stenosis in the fourth decade or later. In 1975, for example, 9255 of 12,775 deaths attributed to rheumatic heart disease were in patients over 50 years of age.[1] The pattern is quite different in developing areas, as in South Africa, where a third of patients have mitral regurgitation usually associated with ongoing rheumatic activity.[127] Left untreated these lesions develop into a severe form of pure mitral regurgitation that requires surgery in the first or second decade of life. Degenerative valvular disease, including mitral stenosis and mixed lesions, is like those seen elsewhere but tends to occur at a younger age.

Another change in group A streptococcal disease in recent years has been the reappearance of serious acute infections, especially bacteremia and streptococcal toxic shock.[4] Since 1980, the number of invasive disease and deaths has increased in several countries. However, the rates in various population-based surveys differ depending upon whether disease was defined as toxic shock, necrotizing fasciitis, or all invasive disease. Surveillance in Ontario, Canada, revealed that the incidence of necrotizing fasciitis (NF) increased from 0.08 cases per 100,000 population in 1992 to 0.49 cases per 100,000 population in 1995, with a case-fatality rate of 13%.[128] In the Netherlands, 1994–2003, annual incidence of all invasive disease peaked in 1996 (4.0 cases/100,000/year) and was at its lowest in 1999 (2.0 cases/100,000/year).[20] Similar rates were noted from Israel.[129] In the United States 5,400 cases of invasive GAS infection (3.5 cases per 100,000 persons) were identified in 2000–2004, with 735 deaths (case-fatality rate, 13.7%). Case-fatality rates for streptococcal toxic shock syndrome were 36 and 24% for necrotizing fasciitis. Rates were highest among elderly persons (9.4 cases per 100,000), infants (5.3 cases per 100,000), and black persons (4.7 cases per 100,000) and were stable over time.[13] Chickenpox has been a major risk factor for invasive disease in children, but cases have declined since the introduction of the varicella vaccine in 1995.[130] Severe invasive infections due to group A, B, C, and G streptococci were reviewed in Denmark from 1999 to 2002. Group A infections occurred at a rate of 2–3/100,000 persons/year. Of particular note was that group G infections rose, mainly among the elderly, from 1 to 2/100,000 during the observation period. Septic shock and toxic shock syndromes were seen in group B, C, and G infections, although not as frequently as with group A streptococci.[19]

Acute poststreptococcal glomerulonephritis is currently a rare disease, as shown in data from Rochester, New York, in Figure 2. There are no contemporary data on rates for nephritis associated with either throat or skin infections in the United States, and no recent reviews. Prospective studies in Alabama (1966–1969) revealed 91 cases of nephritis relative to 1,149 cases of uncomplicated streptococcal pyoderma treated in a clinical setting, for an attack rate of about 8%.[35] Of note, however, is that outbreaks of glomerulonephritis associated with group C streptococci continue to occur, usually in association with unpasteurized dairy products.[131,132]

Group B streptococci emerged in the 1970s as the leading cause of neonatal infection. In the 1980s attack rates of early-onset disease were about 2 per 1,000 live births in defined populations in Chicago, Illinois, and Birmingham, Alabama.[26,133] Several clinical trials demonstrated the potential for prevention of early-onset disease by selective intrapartum antibiotic prophylaxis, which led to the first guidelines issued in 1996 by the CDC, the American College of Obstetricians and Gynecologists (ACOG), and the American Academy of Pediatrics (AAP). Two selection strategies were used: One (ACOG) relied of identification of clinical risk factors, such as prematurity, maternal fever, and prolonged rupture of amniotic membranes. The other (AAP) was based on screening women for vaginal/rectal colonization by group B streptococcal at 35–37 weeks of gestation. Those with colonization and/or risk factors were offered penicillin given intravenously during labor. This resulted in a 65% decrease in early-onset cases to about 0.5 per 1,000 live births from 1993 to 1998, where they remained unchanged through 2001. Meanwhile, further studies in the Active Bacterial Core Surveillance program found that routine antenatal screening prevented significantly more infections than the risk-based strategy.[134] Revised guidelines and updated prophylaxis regimens were published in 2002.[28] Since that

time, rates of early-onset disease have declined and additional 31% to 0.34 per 1,000 live births.[14] Rates among African-Americans have seen the largest decline but are still about twice that in the White population. Early-onset disease rates in Europe vary from 0.3 to 2/1,000 live births, and several countries have prevention guidelines.[16] Clinical studies in France and Italy have found similar reductions in attack rates using a combined culture and risk strategy.[135] Experience using a risk-only prevention in the Netherlands has resulted in only modest reductions from 0.54 to 0.36 cases/1,000 live births, and changes in guidelines have been recommended.[136] Early-onset disease rates are about 2/1,000 live births in South Africa and 0.9/1,000 in Malawi, but prevention strategies are difficult to apply in resource-limited settings.[137]

Late-onset disease, generally defined as occurring in infants older than 7 days, has remained unchanged for over a decade, with rates in the United States about 0.4/1,000 live births.[14] Prematurity is the major risk factor in late-onset disease, occurring in 50% or more of cases.[14,138] Rates are about the same in northern Italy (0.5/1,000 live births),[139] but higher in South Africa and Malawi (about 1/1,000 live births),[137] and considerably lower in the Netherlands (0.14/1,000 live births).[136]

Few data are available on maternal infections due to group B streptococci, such as bacteremia, chorioamnionitis, endometritis, and urinary tract infection. Maternal sepsis occurred in 0.5–2/1,000 deliveries in Alabama, with lowest rates associated with aggressive antibiotic use in mothers undergoing Cesarean section delivery.[140] Rates of chorioamnionitis and endometritis have declined since the introduction of intrapartum prophylaxis.[141]

Group B streptococcal infections in nonpregnant adults have increased between twofold and fourfold over the past two decades.[142] While still occurring at rates of a few per 100,000 population among young and middle-aged adults, those over 65 years are especially vulnerable, with rates of 25/100,000. Predisposing factors, such as diabetes mellitus, malignancy, and residence in nursing homes, are common. Infections of skin and soft tissue, urinary tract, and pneumonia predominate.[143]

Enterococci have been most notable in hospital settings, where endemic infection and outbreaks are common.[121] Vancomycin-resistant enterococci (VRE) now account for about 28% of nosocomial infections.[21] In a study of 24,000 blood culture recorded in 49 US hospitals, 1995–2002, enterococci were found in 9% of nosocomial blood stream infections (about 5/10,000 hospital admissions). The majority of blood isolates were *E. faecium*, of which 60% were VRE.[144] In the only population-based study of invasive VRE, in metropolitan Atlanta, Georgia, disease incidence increased from 0.9/100,000 persons/year in 1997 to 1.7/100,000 persons/year in 2000.[145] *Enterococcus faecium* accounted for over 80% of isolates, followed by *E. faecalis*, and a few *Enterococcus gallinarum* and *Enterococcus durans*. The crude 30-day in-hospital mortality was 40% and was best predicted by three factors: the Charlson comorbidity index, immunocompromise from chemotherapy, and prior antibiotic use. African American patients had a higher mortality rate, attributed largely to higher rates of chronic conditions, especially end-stage renal disease.

In terms of sheer numbers of persons, dental caries caused principally by the mutans streptococci, *S. mutans, Streptococcus sobrinus* and their relatives, probably infects more people than all other streptococci combined. However, the last 40 years of the 20th century saw a remarkable decline in dental caries worldwide, beginning in western Europe and North America.[146] Rates of DMFT (decayed, missing, or filled teeth) were commonly 10/100 surfaces at risk in the 1960s have come down to around 1/100 surfaces by 1988 and have remained relatively stable. The major decline in caries has been attributed mainly to fluoridation programs, fluoride-containing dentifrices, and school dental services. By the mid-1980s about half of school-aged children in the United States and Canadian children had permanent teeth completely free of cavities and restorations.[147] Some of these good news and further reductions in DMFT rates to 1/100 surfaces and below can be ascribed to the introduction of tooth sealants, general improvements in dental care, and changes in parental beliefs and attitudes.[148,149]

Survey methodology for measurement of dental caries is well established and periodically revised.[150,151] Since the populations of developing countries are skewed toward the younger age groups, who have fewer caries relative to the older populations in the developed world, a population-weighted mean DFMT at age 12 is used for global comparisons. By this measure WHO can monitor trends from more than 1,000 surveys submitted to the WHO Global Oral Data Bank, set up in 1970. Some developing countries have seen a rise in DFMT thought to be associated with changes in diet and other factors associated with urbanization.[150] In the absence of fluoridation and adequate dental care, increased sugar consumption may also play a role.[152] Most caries and DMFT data from the developing world now come from regional or national survey or from compilations of published reports.[153]

With the decline in caries incidence in many countries DFMT data may be somewhat less useful, especially for clinical intervention trials, in which individual counts of new decayed, missing, and filled surfaces (DMFS) over a defined period may be better indicators. The decline in caries has also had an impact on the number of patients required

for statistical power in clinical studies.[154] Newer models focus on the evaluation of caries risk, such as Cariogram, a software program that evaluates an individual's caries risk profile and illustrates it in graphic form. The predictive variable which makes the greatest contribution to the model is *S. mutans* count, followed by the DMFT index and the buffer capacity of the saliva.[155]

5.2. Epidemiology and Contagiousness

Of all the streptococcal infections only scarlet fever has been feared as an epidemic disease in the same sense as cholera and plague. In most areas of the world, group A streptococcal disease is endemic, with fluctuations exceeding the normal prevalence levels occurring seasonally or sometimes over an extended period. Localized epidemics of streptococcal pharyngitis or skin infections and acute rheumatic fever are occasionally reported from newborn nurseries, hospitals, nursing homes, day care facilities, and military installations.[156,157] An unusual nursery epidemic occurred when infants were infected from clothing that was improperly cleaned in a hospital laundry.[158] Environmental contamination is thought to be a source of spread within day care facilities, with several studies showing streptococci recovered from environmental surfaces, fabrics, and toys shared by many of the children. A large outbreak of perianal infection prompted a careful investigation that revealed a particular group A streptococcal clone associated with an attack rate of 2–7 per 1,000 children per year in a small rural community in Denmark.[159] Although several urban myths have circulated about contracting streptococcal sore throat from the family dog, household pets are an unlikely source of group A streptococcal infection.[160]

Streptococci associated primarily with the respiratory tract, such as group A and the pneumococcus, cause infections that are initially related to that portal of entry. Of course, some group A strains prefer to colonize the skin and cause impetigo, whereas others affect either skin or throat. The group B streptococci, in contrast, are gut organisms. Asymptomatic gastrointestinal, and to a lesser extent genitourinary, colonization is common. Their infections relate to the aberrations induced by pregnancy, labor, and delivery, and to the unique conditions of infants in the newborn period. The enterococci are also normal gut organisms, but their infections are more generally opportunistic in nature.

Group A streptococci are not considered part of the normal flora of the respiratory tract, and their presence is generally associated with overt infection. Transmission to other persons is greatest from an infected individual, and communicability appears to be dose related. Nevertheless, a large reservoir of asymptomatic carriers, mainly children, exists with endemic rather than epidemic characteristics.[122] Individuals identified as carriers harbor relatively small numbers of organisms. They are at little risk for developing acute disease or sequelae themselves, and they are an uncommon source of new infection.[161] However, the identification of the carrier state, usually defined by the absence of a serologic response, is fraught with difficulties that continue to cloud the relationship between colonization and disease.

Group B streptococci cause serious disease in the perinatal period, but only a small number of infections occur among colonized mothers and infants exposed in utero, during, or after delivery. Maternal group B infections may be initially subclinical and possibly contribute to premature labor or septic abortion.[162] Amnionitis may be present before the onset of fever or other symptoms. After delivery, a previously asymptomatic mother may develop endometritis, usually without bacteremia. Classical puerperal sepsis due to group A streptococci, in contrast, was often transmitted via obstetric personnel and occurred as a fulminant infection after delivery, sparing the infant. With group B streptococci, infected infants are usually exposed in utero to the serotype carried by the mother. Infants with this "early-onset" form of infection are usually bacteremic at delivery and become symptomatic within a few hours of birth.[26,163] Infection is directly related to the size of the inoculum to which the infant is exposed, by swallowing or aspirating infected amniotic fluid. Most infants are lightly colonized and at little risk for infection, whereas those who are infected are almost invariably heavily colonized at birth. Some infants may acquire organisms via the respiratory tract during transit through the birth canal, or from persons other than the mother, and become symptomatic at a later time. Development of the late-onset form of disease may be delayed for days or weeks, and only about half of these infants will be infected by an organism acquired at birth or from the mother.[26,138]

Pneumococci are often thought of as normal respiratory flora, but pneumococcal infections are not opportunistic in the sense that they are caused by any pneumococcus that happens to reside in the nasopharynx. Most infections are due to new types not previously carried by a given individual. This was first observed in the classical investigations of Hodges and MacLeod on pneumonia at a United States Air Force training facility in the 1940s.[164] Within about 6 weeks of arrival, new recruits often acquired one of a small number of "epidemic" types (1, 2, 4, 5, 7, and 12) prevalent at the base. Although the rate of carriage of the epidemic types was relatively low, the "infectivity factor" (measured by the ratio of cases of pneumonia to the number of carriers) was much higher than that of other types commonly carried. Similarly, infants in our prospective study frequently carried one of several common types for prolonged periods, but when

they develop otitis media it was usually within 4 weeks of acquiring a type they had not carried previously.[165] This epidemiologic relationship has been nicely confirmed in the Finnish Otitis Media Cohort Study.[166]

The concept of dental caries as a transmissible infectious disease was drawn from animal studies in the 1960s. *Streptococcus mutans* has been implicated as a major pathogen in caries, and it appears that most infants acquire *S. mutans* strains from their mother.[7,107] These observations have been confirmed using molecular methods in a prospective studies of acquisition and infection.[8,107] They further developed evidence for a discrete "window of infectivity" between 18 and 30 months of age, coinciding with the emergence of the 20 primary teeth. Children who did not acquire *S. mutans* during this period were at much lower risk for caries, at least through 6 years of age. To develop stable colonization *S. mutans* requires nonshedding tooth surfaces over a period of time. Children generally harbor several *S. mutans* genotypes, with a tendency to form stable colonization by strains transmitted from the mother.[107] Based on epidemiologic evidence from caries prevalence surveys, it is postulated that a second window of infectivity may exist coincident with the emergence of permanent teeth between 6 and 12 years of age.

Streptococcus suis is an emerging zoonotic pathogen found in pigs raised in suboptimal conditions. It affects humans who have direct contact with pigs and pork, with little evidence for person-to-person spread among humans. In three outbreaks in China, in 1998, 1999, and 2005, over 200 people were infected, and 53 died. Nearly three quarters of cases reported have been from China, Thailand, and the Netherlands.[11]

5.3. Geographic Distribution

Streptococcal diseases are of worldwide importance. Group A streptococci appear to be well adapted to humans living in temperate or tropical climates, although differences in the temporal distribution and perhaps the characteristics of disease may vary. In some tropical areas, groups C and G streptococci are more frequently isolated in cases of pharyngitis than are group A strains. As noted above, group B streptococcal carriage is widespread, but infection rates are highest in North America and western Europe, with lowest rates reported from the United Kingdom, northern Europe, and parts of Asia. Pneumococci are the leading cause of bacterial respiratory infection in all parts of the world. In some areas, such as sub-Saharan Africa where seasonal epidemics of meningococcal disease are common, pneumococcal disease remains endemic and accounts for many cases of meningitis throughout the course of the year.

Dental caries occur worldwide. Although caries have been more common in industrialized areas than in developing countries,[150] recent international comparisons have been encouraging, with about 50% of children caries free across 17 countries surveyed.[148] Sweets and sugary drinks continue to play a modest role, but the most important factor now is seen to be parental beliefs and attitudes (the "Brushing Parental Efficacy Factor") that promotes earlier and better supervision of tooth brushing and dental care.[148] Although this has been attributed in part to the higher use of sucrose and refined foodstuffs and social changes associated with urbanization, the major factors remain lack of dental care. The incidence of caries is mitigated to some extent by the availability of artificial fluoridation in dentifrices and water supplies.[152] Caries have always been less common in geographical areas with natural fluoridation.

5.4. Temporal Distribution

Group A streptococcal infections follow characteristic seasonal patterns. In northern parts of the United States streptococcal pharyngitis is typically seen over the winter months, peaking in February or March, while skin infections occur mainly in the summer. Figure 3 illustrates this pattern in surveillance data from private pediatric practices in Rochester, New York, for the 12 years 1977–1988. In the southeastern states there is both a late fall and a late winter peak of respiratory infection, coinciding with the beginning of school in the fall and with increased indoor activity or crowding during colder months. Seasonal variation is less evident in tropical or subtropical areas, although gathering of children at school or other institutions appears to increase the incidence of disease at certain times of the year. Streptococcal skin infections are most common in the rainy season in tropical areas. Such conditions favor the exposure of unprotected skin to the assault of minor trauma and the bites of mosquitoes and other insects. Organisms present on the skin surface, or rarely from the respiratory tract, may be inoculated into damaged skin by itching or scratching.

In temperate climates pneumococcal infections tend to peak in winter months. The disease incidence is not related to the carriage rate, which varies only slightly over the year, but parallels the markedly seasonal rate of acquisition of new strains.[165] In the study of Hodges and MacLeod there was also a strong correlation of pneumococcal lobar pneumonia with the seasonal peaks of influenza virus infection.[164] Present day findings suggest that the association with influenza is rather weak, although a stronger association may be noted for respiratory syncytial virus.[167] In the "meningitis belt" of Africa pneumococcal meningitis epidemics usually occur along with meningococcal epidemic

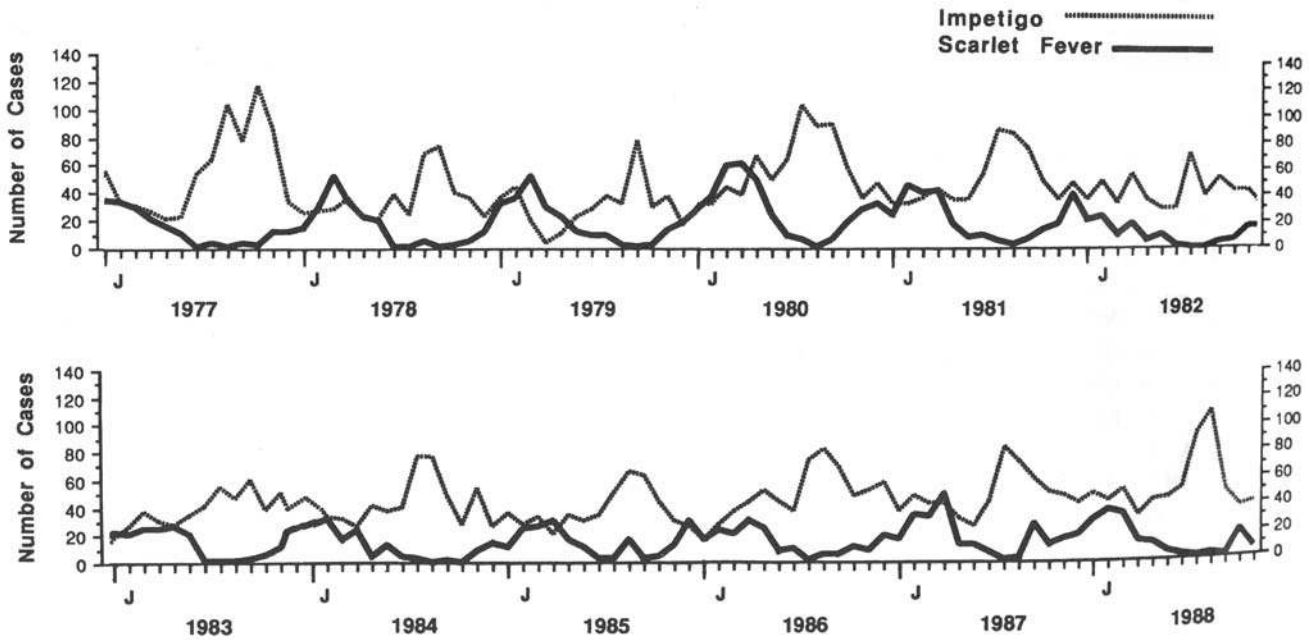

Figure 3. The number of cases of scarlet fever (*solid lines*) and streptococcal impetigo (*dotted lines*) seen monthly in private pediatric practices participating in streptococcal surveillance studies in Rochester, New York, 1977–1988. The data were kindly provided by Caroline Breese Hall, University of Rochester.

season, beginning with the dry weather in February–March. This seasonal pattern is not understood but may involve increase indoor crowding because of the weather and also change in the respiratory mucosa in response to severe drying.[168]

5.5. Age

Group A streptococcal pharyngitis is uncommon in children under 4 years of age. It increases in frequency as children enter school, peaking at 9–12 years of age. These children are the primary source of respiratory infections that occur among families and are thus a source of exposure for parents and other adults in the household. Streptococcal impetigo, in contrast, is chiefly a disease of younger children. It is frequently seen in toddlers and children under 4 and typically reaches a peak incidence at about 6 years of age. Adolescents tend to be subject to milder and often self-limited disease.[122,169]

Group B streptococcal remains a common cause of sepsis and meningitis in neonates and infants up to about 3 months of age.[14] Prematurity is the major risk factor in late-onset disease.[138] Group B streptococci are a common though sometimes disregarded cause of urinary tract infection among adult women, especially during pregnancy, and are an important cause of perinatal and postpartum infection.[162] This has been associated with late abortions and problems of the perinatal period. Rarely does an older child or adult develop a serious infection in the absence of some compromise of normal host defenses. Older adults, however, account for as much as 40% of all group B streptococcal infections. Most common are cases of cellulitis or pressure sores, urinary tract infection, bacteremia, and pneumonia. These are often associated underlying conditions, especially diabetes mellitus, nursing home residence, cardiac disease, and malignancy.[143]

Pneumococcal disease is seen in all age groups, but principally affects the very young and the very old. Among children, 70% of meningitis and bacteremia occur in those under 24 months of age, peaking at 8–12 months of age. The introduction of a 7-valent conjugate vaccine in 2000 resulted in a 60% reduction in invasive disease with the largest decline in infants <12 months of age.[170] The incidence of bacteremic infections increases sharply with age over 55 years, and the case-fatality rate in this group is over 80%. A welcome indirect effect of the 7-valent pediatric vaccine has been the reduction of pneumococcal disease among adults over age 65.[15,171]

Serious infections by enteric and oral streptococci are less subject to the effects of age than to the natural defenses of the host. Low-birth weight babies are increasingly infected by group D and viridans streptococci and

enterococci, perhaps because of the kinds of interventions required for the management of very premature infants or changes in patterns of antibiotic use. Nosocomial infection caused by enterococci spans the range of age, but is most common among older hospitalized adults.[12]

Dental caries is a chronic disease that continues throughout life.[149] Longitudinal studies from diverse localities show that rates of development of new caries are about the same in adults as they are in children, although older adults are more likely to get root caries and gum disease. However, as noted in Section 5.2, there appears to be an age-specific window of acquisition of *S. mutans* at 18–30 months of age that correlates with subsequent risk of caries development.[8]

5.6. Sex

Sex is not a factor in the development of streptococcal disease, except as it relates to pregnancy and to specific genitourinary infections, especially those caused by group B streptococci.[162] These organisms may be transmitted by close, intimate, or sexual contact, but genital colonization is not associated with symptoms in either sex.[172] Colonization may be higher in women during the first half of the menstrual cycle, perhaps because of greater adherence to vaginal epithelial cells at this time. The peptostreptococci are recognized in pelvic inflammatory disease but are rarely encountered (or looked for) elsewhere.

5.7. Race and Genetic Factors

No one is spared from susceptibility to streptococcal infections. Much of the association between race and susceptibility can probably be accounted for extrinsic factors, such as poverty, crowding, and lack of medical care. Nevertheless, there is growing evidence that certain persons within racial groups may have some genetic host predisposition. Studies of histocompatibility leukocyte antigen (HLA) distributions point to increased risk of rheumatic fever for blacks expressing the DR2 phenotype and for whites with the DR4 phenotype.[75] Agammaglobulinemia and IgG subclass deficiencies are associated with recurrent pneumococcal infection. Various complement deficiencies, especially that of the second component (C2), should also be considered in children with repeated pneumococcal disease. Children and adults with sickle cell disease are at increased risk because of functional asplenia, which develops after repeated episodes of splenic infarction. Down's syndrome and cleft palate are associated with increased frequency of otitis media due to pneumococci and other organisms.

5.8. Occupation

Occupation is rarely a factor in the development of group A streptococcal infections. Physicians, nurses, and laboratory workers in close contact with infected patients or their cultures seldom develop disease. Epidemics of skin infections have occasionally appeared in meat packers, and foodborne.[132,173] Group B streptococci are a major cause of mastitis in cattle. Spread is thought to occur mainly via the hands of dairy workers from human or bovine sources. Molecular studies suggest that at least two lineages of strains from bovine mastitis are very closely related to some isolates causing human disease.[174] Consumers of raw infected milk may become colonized with group B streptococci but do not appear to be at risk for disease. Groups A and C streptococcal diseases have occasionally been associated with milk-borne transmission.[132] Group C infections have also been associated with exposure to horses and other animals. Workers in the pork industry occasionally develop meningitis due to *S. suis,* as noted above.[11] *Streptococcus iniea,* a common fish pathogen, has been associated with infections in workers at a fish farm and others handling or cooking fish.[132]

5.9. Other Settings and Predisposing Factors

Family studies of respiratory bacteria have indicated that the group A streptococcus and the pneumococcus enter a family unit most commonly via the school-aged children.[122] These organisms spread rather slowly to other family members, some becoming colonized and very few developing overt infection. Spread is often facilitated by concomitant viral respiratory infections. Socioeconomic factors, crowding, and substandard housing have frequently been cited as contributing to the spread of these organisms and to the development of acute rheumatic fever and bronchopneumonia. Schools, day care centers, nursing homes, and long-term care facilities may experience periodic problems with group A streptococci.[175] Spread of pneumococci generally occurs slowly with little consequence in day care centers, but occasional outbreaks of serious disease have been reported in child care and nursing home settings.[176]

The military has been associated for over a century with increased risk for developing streptococcal disease, especially acute rheumatic fever and pneumonia.[164,177] Our present understanding of the epidemiology of rheumatic fever and methods for antibiotic prophylaxis date from important studies done in the US Armed Forces during and after World War II. Rates of streptococcal pharyngitis are much lower in recruit camps where penicillin prophylaxis was routinely used. In one report, however, antibiotic prophylaxis was not effective until penicillin-allergic recruits,

who continued to harbor streptococci, were given oral erythromycin.[178]

Nosocomial spread of groups A and B streptococci continues to be reported, especially from obstetric and surgical services and newborn nurseries.[142,156] Sources of infection may be other patients or personnel who carry organisms in the nose, throat, skin, vagina, or anus. Enterococcal infections in neonates and surgical patients usually originate from the patient's own flora, under the influence of physical interventions and antibiotic therapy.[12,58,121] Intraabdominal wounds, burns, intravascular catheters, and the urinary tract are the most frequent sites associated with nosocomial enterococcal bacteremia. Pneumococci are important but infrequent causes of nosocomial outbreaks.[176]

Predisposing host factors may be genetic or acquired, such as sickle cell disease, immunodeficiency, or splenectomy. Splenectomized patients have a 50- to 200-fold greater risk of serious bacteremic infection.[179] Surgical repair, rather than removal, of a traumatized spleen is frequently possible and always preferred to removal. Overall, about a fourth of children with pneumococcal bacteremia or meningitis have some underlying condition or host defense abnormality, and risk for these children persists well beyond 24 months of age. Patients with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) are at particularly high risk of bacteremic pneumococcal infection.[180] Intravenous drug abuse, also a known AIDS risk factor, is associated with an increase in group G streptococcal infection.

6. Mechanisms and Routes of Transmission

The transmission of streptococci, introduced in Section 5.2, depends on factors such as the usual ecologic niche of the species, its occurrence as part of the normal flora, and the ease with which it may be carried by hands, in secretions, or possibly in droplets. The group A streptococci are transmitted principally by direct contact. Contagiousness is greatest during acute respiratory infection, whereas the chronic carrier is a relatively low risk as an infectious source. This probably reflects the fact that development of infection requires a fairly large inoculum. About 100 organisms are required to infect adult volunteers by directly inoculating the tonsils and pharynx with organisms on a cotton swab. Although streptococci may occur in droplets and survive in dust, an individual is unlikely to acquire a large enough inoculum to become infected from these sources. Streptococci recovered from contaminated blankets and dust may also be less infective. Direct transmission of respiratory secretions may occur via hands, person-to-person contact such as kissing, or projection of large droplets during coughing or sneezing. Treatment of infected persons eliminates the risk of spread within 24 h, permitting resumption of work or school activities as soon as constitutional symptoms have abated.[181]

Pneumococci are thought to be transmitted by similar routes.[182] Coughing is a more regular feature of pneumonia than it is of other pneumococcal infections or of streptococcal pharyngitis. Transmission appears to be favored by symptoms of cold and coryza. Dust particles may harbor pneumococci but do not play a significant role in transmission.[164] Direct spread of secretions containing viable organisms is the most likely source. Covering one's mouth with a hand may deflect a cough or sneeze, but the hand may then transmit fresh secretions.

Large milk-associated epidemics of group A streptococcal disease such as occurred in early in the last century have now been essentially eliminated by the widespread adoption of pasteurization.[132] Small outbreaks of group A and C infections continue to be seen with contaminated prepared foods, such as egg salad, or with cheese and dairy products from cows or goats.[131,132] Despite the prevalence of group B streptococci in bovine mastitis, milk-borne group B infections have not been reported. However, some virulent group B strains appear to be genetically related to lineages of bovine origin.[174]

Skin infections due to group A streptococci are often caused by serotypes different from those associated with throat infections (see Table 3). Similarly, certain corresponding *emm* types are markers for strains with a strong preference for skin infection.[38,75] Streptococci may occur on normal skin but do not cause infection unless there is a break in the cutaneous epithelium. Minor injuries such as scratches, abrasions, cuts, or insect bites may become points of entry. Mosquito bites are an especially common site of inoculation, where organisms are rubbed into the wound during itching. In Trinidad, streptococcal impetigo may be transmitted by flies of the genus *Hippelates*, which feed on open skin sores. Streptococci from the nasopharynx may be transmitted to skin sites, but it is more common for the skin to be colonized first and the throat later. Classical erysipelas, in contrast, is thought to be transmitted via the respiratory tract, either from the patient or from a caretaker. Erysipelas is occasionally seen following superinfection of chicken pox lesions.

The group B streptococci causing early-onset perinatal infections are those carried by the mother in the lower gastrointestinal and genitourinary tracts. Organisms may enter the amniotic cavity following rupture of amniotic membranes, but the fetus may become infected with membranes intact. Although rupture of membranes for greater than 12 h is a recognized risk factor for ascending infection,

the duration of labor is also important, perhaps because of the entry of organisms via microscopic defects in the membranes. Among twins, who have a higher rate of infection than singletons, it is usually the first twin who is closer to the source of infection and at greater risk. Once the streptococci have entered the amniotic fluid, they proliferate rapidly and are aspirated or swallowed by the fetus. Late-onset infections may have a maternal source in about half of cases, with colonization occurring at delivery.[26,138] Other infants may acquire streptococci later from persons outside the immediate family, presumably via the oral or respiratory route. Late-onset and recurrent infections have also been transmitted by mother's milk in cases with mastitis, asymptomatic colonization, or banked breast milk.[183]

Oral streptococci are part of the normal flora and are acquired early in life from the mother and family members.[7,8,107] Enteric streptococci generally cause opportunistic infection only after perturbations of normal defenses. Nosocomial infections are usually due to a patient's own flora. Transient bacteremia may occur with dental manipulation, transurethral prostate resection, or gynecologic and gastrointestinal surgery. Patients with known history of valvular heart disease or artificial heart valves are at higher risk for developing endocarditis due to otherwise "benign" streptococcal species. In such cases a prophylactic antibiotic is administered just prior to the dental or surgical treatment (see Section 9.2). Enterococcal infections may be similarly opportunistic or nosocomial in origin.[12]

7. Pathogenesis and Immunity

7.1. Pathogenesis

The development of infection involves a multitude of interrelated bacterial and host factors that vary enormously among streptococcal species. The biologic characteristics associated with virulence among various streptococci are summarized in Section 4; certain host factors and modes of transmission are noted in Sections 5.9 and 6. The pathogenic process is not clearly understood for any streptococcal disease, but it may be useful to consider three general stages.

First, organisms are acquired by the host and either succeed in colonizing their preferred sites or are eliminated by host defenses at the epithelial surface. For many streptococcal species the specific mechanisms of adherence are known.[75,78,92,184] Adherence may be important in the establishment of colonization but is not necessarily a property that distinguishes virulent from commensal species or strains. To ward off bacterial invasion the host has epithelial barriers, mucus layers, and secretions containing enzymes and antibodies.

The second stage begins when organisms succeed in breaching local defenses and enter the epithelial and subepithelial tissues, or in the case of *S. mutans* get into and through the tooth enamel.[75,92,184] Most of the acute pathologic effects of group A streptococci occur at this stage by causing pharyngitis or skin infection, with invasion of the submucosal or subepidermal layers. This is frequently accompanied by lymphadenitis but rarely progresses to bacteremia. In pneumococcal pneumonia and in otitis media the initial insult is not a direct breach of epithelium but rather the invasion of a normally sterile compartment; symptoms of disease ensue as organisms multiply and induce inflammation in surrounding tissue. The host responds with nonspecific secretory and serum forces, including the release of vasoactive and chemotactic mediators, activation of the alternative complement pathway, and with the mobilization of neutrophils and tissue macrophages. Eventually, specific secretory and serum antibodies develop and contribute to resolution of the disease.

The third stage is systemic infection, in which organisms multiply in blood and tissues. Severe streptococcal infections, including streptococcal toxic shock, depend upon the organism's ability to evade host defenses until it establishes a sufficient mass of growth to cause systemic manifestations. The M proteins protect against phagocytosis and also down-regulate complement activation on the bacterial surface.[73] C-5 peptidase is an enzyme that inactivates complement C5a and decreases chemotaxis and secondary inflammatory responses.[87] Spread of infection within the tissues may be facilitated by the action of hyaluronidase and proteinases. Shock is probably mediated by tumor necrosis factor-α (TNFα), interleukin (IL)-1β, and IL-6, all of which may be induced by pyrogenic toxins (SPE), streptolysin O, and cell wall breakdown products. Further alterations in host physiology occur by cytokine activation and by direct and indirect effects on hemodynamics, metabolism, and the function of individual organs.[4,185,186]

Similar mechanisms are involved in acute group B streptococcal sepsis.[92,187] Early-onset infections usually begin in utero, and it is suspected that the organisms gain access to the circulation by breaching the gastrointestinal or pulmonary epithelial barriers. The organisms may be actively taken up by pulmonary alveolar cells acting as nonprofessional phagocytes, which are incapable of killing the organisms preventing tissue invasion. Alternatively, the organisms can cross the epithelial barriers by transient openings in the cell junctions.[188] Group B streptococci also have mechanisms to evade the inflammatory responses of the host, including the antiphagocytic properties of the polysaccharide capsules,

a C5a inactivating enzyme similar to that of group A streptococci, and the c protein, which binds IgA in a nonimmune fashion. The early manifestations of severe disease depend upon the inflammatory responses mediated by both specific and innate host defense factors. Group B streptococcal surface structures and breakdown products, especially cell wall peptidoglycan, interact directly with macrophages and monocytes promoting release of proinflammatory cytokines. Cell wall activates C3 complement via the alternative pathway, and both peptidoglycan and lipoteichoic acid (LTA) interact with components of the Toll-like receptor (TLR) system, which in turn promotes cytokine responses. Tissue damage due to hemolysins and other toxins further the inflammatory response. While the initial inflammatory response is often minimal in infants, despite the presence of bacteria in the lung or other tissue, localized, overexuberant responses in the central nervous system appear to play a major role in disturbing the blood–brain barrier, opening the way to development of meningitis.[92,187]

The most severe infections, particularly streptococcal toxic shock syndrome, have all the elements of invasive disease, and in addition have the effects of streptococcal superantigens.[75,89,185,186] These include streptococcal pyogenic exotoxins (SPE) A, B, C, F (mitogenic factor), G, H, J, and are much like the staphylococcal toxic shock toxin (TSST-1) and staphylococcal exotoxins SE A–E and H. The absence of neutralizing antibodies to these toxins is associated with increased risk of severe disease.[189] Superantigens are a family of protein toxins that activate the immune system by binding directly to both the MHC class II molecules of antigen-presenting cells and the Vβ T-cell receptor, causing nonspecific activation of up to 30% of the entire T-cell population. This in turn causes massive release of cytokines, including TNFα, interferon-γ, IL-2, and IL-6. More T and B cells are recruited to the site of infection, resulting in further release of IL-1, TNFα, and other mediators. The triggering of an overexuberant host response is thought to play a large role in hypotension, disseminated coagulopathy, and multiorgan failure seen in toxic shock syndrome.

The pathogenesis of the nonsuppurative sequelae of group A infections has yet to be fully elucidated. Examples of the cross-reactivity between M proteins and components of heart, brain, and connective tissue have now been convincingly confirmed and add weight to the long-held hypotheses of autoimmune mechanisms for rheumatic valvular disease, Sydenham's chorea, and skin manifestations.[75] Although multiple complex factors appear to be involved in disease process, these and other studies have identified M protein epitopes that cross-react with myosin, DNA, and α-helically coiled proteins such as tropomyosin, actin, and keratin. Antigenic mimicry between cell wall carbohydrate moieties and cytokeratin may eventually help explain the occurrence of erythema marginatum, subcutaneous nodules, rheumatic arthritis, and perhaps streptococcal-associated guttate psoriasis. The diverse manifestations of acute rheumatic fever might be explained in part by the specificity and titer of antibodies cross-reactive with different tissue components. In a similar fashion, acute glomerulonephritis may involve the development of antibodies that cross-react with basement membrane collagen and laminin.[75] The cationic charge of the antigens may also influence their affinity for the glomerular basement membrane and the nature of immune complexes formed. Another feature of nephritogenic streptococci is the presence of a nephritis strain-associated protein.[85] This distinctive low-molecular-weight streptokinase is a plasminogen activator and could induce proliferation of cells, release of inflammatory products, and activate complement, thus contributing to known pathologic features of the disease.

The pathogenesis of dental diseases has been described as "examples of ecological catastrophes."[190] Caries development involves dynamic relationships among dental plaque organisms, dietary carbohydrates, and mucosal host defenses. Fermentable carbohydrates, especially sucrose, favor the adherence of mutans streptococci to the tooth surface by several different mechanisms, including glucan-binding and salivary-binding proteins. *Streptococcus mutans*, together with *Streptococcus sobrinis,* lactobacilli, and other bacteria form biofilms on the tooth surface. The biofilms have an extracellular water-insoluble carbohydrate matrix which helps stabilize and protect the bacterial colonies and concentrate acids from fermentation, which in turn lower the pH, and aid in demineralization of tooth enamel. This process is countered by the host by the buffering capacity of saliva and defensive components, such as lysozyme, lactoferrin, and secretory IgA. Specific antibodies to *S. mutans* surface proteins can inhibit sucrose-dependent adherence and interfere with biofilm formation.[107,184]

7.2. Immunity

Specific immunity to streptococcal infections is thought to depend on the development of antibodies to capsular and other surface determinants. Antibody assays for various streptococcal antigens have been noted in Section 3.4.2, and current developments in streptococcal vaccines are further discussed in Section 9.6. Although most of our knowledge of the immune response relates to the occurrence of antibodies in the serum, recent studies of mucosal immunity suggest that the first line of host defenses are at the local level. The precise role of secretory antibodies in preventing, modifying, or eradicating bacterial colonization is not presently understood. Conversely, the effects of bacterial antigens at

respiratory and gastrointestinal sites are poorly understood in regard to the systemic antibody response and the development of autoantibodies. In some cases it is likely that the organisms have developed a form of mimicry to confuse or evade the immune response of the host. Many streptococci have antigens that cross-react with other organisms, common foodstuffs, or components of the host's own tissue. Antibodies undoubtedly have functions other than protection against disease. They are known to be important in the recovery from established infection and probably function in the removal of antigens from local and systemic sites.

Assays for group A streptococcal antibodies (Table 5) are used clinically to determine if a patient has had a recent infection.[72] Although humans normally make antibodies to streptolysin O and other extracellular components, only antibodies to M proteins are associated with protection against subsequent disease.[73,75,185] Serum IgG antibodies to M proteins arise in response to infection or immunization and can initiate bactericidal activity in whole blood opsonophagocytic assays. These antibodies, however, are not as efficient as secretory IgA antibodies in protecting mice against infection via the intranasal route. Intranasal immunization of volunteers with purified M protein resulted in greater resistance to colonization with live streptococci than did subcutaneous immunization, and serum antibody response was not a reliable predictor of resistance to pharyngitis. At present, group A vaccines remain experimental, but it appears that local immune mechanisms may be more efficiently utilized and less likely to result in systemic side effects.

Antibodies to the capsular polysaccharides of group B streptococci are thought to mediate protection against systemic invasion. This concept is based on the finding that few infants with group B streptococcal disease have antibodies to the offending type, and that antibodies are protective against bacterial challenge in animal models.[191] Naturally occurring antibodies in mothers are often of the IgM class and do not readily cross the placenta, and less IgG antibody is transferred to the premature than to the term fetus. Protective levels of IgG seem to vary with serotype, and protection increases as fetuses receive more maternal IgG at > 34 weeks gestation. In a prospective study of infection levels have been empirically estimated to be ≥ 5 μg/ml for type Ia and ≥ 10 μg/ml for type III.[192,193] Despite the presumed importance of antibodies, it should be pointed out that the prevalence of group B streptococcal antibodies among pregnant women is generally low, with only 7–23% sera having >2 μg/ml against types Ia, Ib, II, III, and V in a defined population.[194] Thus, the majority of infants are "antibody deficient," whether colonized or not, yet only a small number develop disease, even when exposed to infected amniotic fluid in utero.[195] The presence of mucosal antibodies may modify colonization, but so far a clearly defined role for secretory immunity is not apparent.

Most of our knowledge of pneumococcal immunity comes from studies of purified polysaccharide vaccines. Adults respond well to most of the antigens, but infants respond poorly. Conjugate vaccines improve the immunogenicity of vaccines by coupling the polysaccharides to protein carriers to elicit T-helper cell involvement in the immune response. Although an IgG level of >0.2 mg/ml has been used as a marker of vaccine response, there is no consensus as to what constitutes a protective serum antibody level.[196]

8. Patterns of Host Response

8.1. Clinical Features

The manifestations of streptococcal diseases are remarkably diverse. Their clinical presentation, diagnosis, and therapy are discussed in detail in many of the medical, pediatric, and infectious disease textbooks. The most common and most important diseases caused by the major streptococcal group are listed in Table 6. Diseases associated with other streptococci are noted in Tables 1 and 2.

The typical form of group A streptococcal respiratory disease in children and adults is acute exudative pharyngitis. The onset is abrupt, with fever, chills, a sore throat with pain on swallowing, malaise, headache, often with abdominal pain, nausea, or vomiting. On physical examination, the pharyngeal mucosae are erythematous, edematous, and streaked with a purulent nonadherent exudate over the tonsils or posterior pharynx; petechiae may be present. The anterior cervical lymph nodes may be enlarged and are usually acutely tender. In young children the findings may be less specific, often with fever and lymphadenitis but relatively little inflammation of the upper respiratory mucosae. Mild or subclinical infection may occur at any age and may be missed. This is of concern because up to half of patients developing rheumatic fever do not give a clear history of an antecedent sore throat. With scarlet fever the pharyngitis is accompanied within about 24 h by a fine red exanthem beginning on the trunk and intertriginous areas, later spreading to the extremities. The face is usually spared, but the tongue may be inflamed with a "strawberry" appearance. Careful auscultation of the heart should be part of the physical examination on all patients with acute streptococcal sore throat or scarlet fever.

Streptococcal impetigo may appear as single lesions of the epidermis, frequently on the lower extremities, spreading to other areas as new insect bites or breaks in the

Table 6. Diseases Associated with Major Streptococcal Groups

Group A streptococci	Group B streptococci	Pneumococci	Enterococci
Most common	Early-onset neonatal disease	Infants and children	Nosocomial
Pharyngitis/tonsillitis	Undifferentiated sepsis	Otitis media	Bacteremia
Scarlet fever	Meningitis	Conjunctivitis	Intra-abdominal infection
Impetigo/pyoderma	Pneumonia	Pneumonia	Surgical wounds
Cellulitis	Bacteremia	Bacteremia	Burn wounds
Less common	Maternal infections	Meningitis	Vascular catheter
Toxic shock syndrome (Table 7)	Amnionitis	Epiglottitis	Urinary tract infection
Peritonsillar abscess	Endometritis	Adults	Postpartum infections
Mastoiditis	Urinary tract infection	Sinusitis	Community acquired
Sinusitis	Bacteremia/sepsis	Pneumonia	Urinary tract infection
Otitis media	Septic abortion	Pleural empyema	Endocarditis
Erysipelas	Bacteremia	Endocarditis	Biliary infection
Pneumonia/empyema	Late-onset neonatal disease	Meningitis	Pelvic infection
Puerperal sepsis	Meningitis	Endocarditis	
Meningitis	Bacteremia/sepsis		
Endocarditis	Bone and joint infection		
Proctitis	Skin and soft tissue infection		
Vulvovaginitis	Otitis media		
Nonsuppurative sequelae	Omphalitis		
Acute rheumatic fever			
Acute glomerulonephritis			

skin become infected. Early lesions are pustular and rapidly develop into mature lesions about 1 cm in diameter with a characteristic honey-like crust. Lesions may become concomitantly infected by staphylococci, which may be resistant to penicillin therapy. Erysipelas is a serious superficial soft tissue infection that extends into the subcutaneous lymphatics and appears with a rapidly advancing well-demarcated border. Erysipelas often involves the face, a surgical wound, an umbilical stump, or a chicken pox lesion. The patient is febrile, toxic, and may be bacteremic. Necrotizing fasciitis is a deep-seated infection of subcutaneous tissue that destroys fascia and fat but may also destroy skin and muscle. Patients may be diabetic or otherwise debilitated. Recently reported cases have occurred mainly in previously healthy individuals who had trivial or inapparent trauma at the affected site. A hallmark, though nonspecific, is the rapid progression from tenderness to severe pain at the site of infection. Infections may become gangrenous and require surgical debridement or fasciotomy.

Streptococcal toxic shock has been observed with varying frequency in Europe and North America during the past decade or more.[4,13,20] Persons may be affected at all ages, usually without predisposing or underlying diseases. Most cases involve a skin or soft tissue focus of infection or pneumonia (as in the case of puppeteer Jim Henson), and most patients are bacteremic. In children a large proportion of cases are associated with infected chicken pox lesions, but this has almost disappeared as a risk factor since the routine use of varicella vaccine has been implemented. Criteria for diagnosis of streptococcal toxic shock are given in Table 7.[197] This syndrome differs from other serious streptococcal infections, and to some extent from staphylococcal toxic shock, by the rapid development of hypotension and multiorgan failure early in the course of infection. Streptococcal toxic shock is rarely associated with sunburn-type rash; however, such a rash is common in staphylococcal toxic shock syndrome.

The nonsuppurative sequelae of group A infections may present acutely or insidiously. Acute rheumatic fever varies greatly in its manifestations. The diagnosis was made with the guidance of the Jones Criteria (updated in 1992),[198] described in Table 8. The onset is typically abrupt, with fever and polyarthritis. Myocarditis or valvulitis, most commonly involving the mitral valve, occurs in about half of patients suffering their first attack. Carditis may be the only major manifestation in some patients and may develop insidiously, presenting as heart failure without any clear history of prior rheumatic fever or obvious streptococcal infection.[3,198] Because of difficulties in making the diagnosis, other conditions, such as collagen-vascular diseases and infective endocarditis, must be considered whenever acute rheumatic fever is suspected. Acute glomerulonephritis presents fewer diagnostic problems. A recent skin or throat infection is usually evident by examination, history, culture, or antibody tests. The urine is dark, containing many red blood cells and casts. The patient usually has edema and

Table 7. Proposed Criteria for Diagnosis of Streptococcal Toxic Shock[a]

I. The isolation of group A streptococci
  A. From a normally sterile site, such as blood, CSF, surgical wound, pleural fluid, etc.
  B. From a nonsterile site, such as throat, open wound, or superficial skin lesion, or vagina
And
II. Clinical signs of severity
  A. Hypotension; systolic blood pressure ≤90 mmHg in adults or <5th percentile for age in children
  And
  B. Two or more of the following:
    1. Renal impairment evidenced by elevated creatinine ≥2 mg/dl (177 μmol/l) or twice the upper limit of normal for age; or, for patients with preexisting renal disease, ≥2 times baseline level
    2. Coagulopathy: thrombocytopenia (<100,000/mm^3) or disseminated intravascular coagulation, defined by prolonged clotting time, low fibrinogen, and presence of fibrin degradation products
    3. Liver involvement: elevated liver enzymes or total bilirubin ≥twice the upper limit of normal for age; or, for patients with preexisting liver disease, ≥2 times baseline level
    4. "Adult" (acute) respiratory distress syndrome (ARDS), defined by onset of diffuse pulmonary infiltrates and hypoxemia in absence of cardiac failure; or evidence of diffuse capillary leak manifested by acute generalized edema, or pleural or peritoneal effusions with hypoalbuminemia
    5. Generalized erythematous macular rash, which may desquamate
    6. Soft tissue necrosis including necrotizing fasciitis, myositis, or gangrene
A *definite* case is defined by isolation of group A streptococci from a normally sterile site (IA) plus hypotension (IIA) and supporting clinical signs of severity (IIB). A case is defined as *probable* if the culture was from a nonsterile site (IB) and it fulfills the clinical signs of severity (IIA + B), when no other etiology for the illness can be identified

[a]Adapted from The Working Group on Severe Streptococcal Infections.(196)

Table 8. Jones Criteria (Revised) for Guidance in the Diagnosis of Acute Rheumatic Fever, as Recommended by the American Heart Association

Major manifestations	Minor manifestations
Carditis	Clinical
Polyarthritis	Fever
Chorea	Arthralgia
Erythema marginatum	Previous rheumatic fever or rheumatic heart disease
Subcutaneous nodules	
	Laboratory
	Acute phase reactions: abnormal erythrocyte sedimentation rate, C-reactive protein, or leukocytosis
	Prolonged P–R interval

Supporting evidence of streptococcal infection:
  Positive throat culture for group A streptococcus or positive rapid streptococcal antigen test
  Increased or rising antistreptolysin O or other streptococcal antibody
The presence of two major, or one major and two minor, manifestations *plus* evidence of a preceding streptococcal infection indicates a high probability of rheumatic fever
Manifestations with a long latent period, such as chorea and late-onset carditis, are exempt from the latter requirement. The WHO Study Group recommends that the following groups be considered separately and exempted from the Jones criteria: "pure" chorea, insidious or late-onset carditis, and rheumatic recurrence(197)

elevated blood pressure; the blood urea nitrogen and creatinine are usually elevated and the C3 complement level is low. With appropriate acute care, nearly all patients have a complete recovery.

Group B streptococcal disease in the neonate usually begins in utero with nonspecific symptoms appearing within the first few hours of birth.(26,163) Unexplained apnea, respiratory distress, temperature instability, or poor feeding may be the only clues to early-onset disease. Infection usually takes the form of undifferentiated sepsis with, or more often without, meningitis. The disease is well advanced by the time hypoxia, cyanosis, acidosis, or vascular collapse becomes obvious. Lung involvement is frequent but the chest X-ray is typical of hyaline membrane disease more often than of discrete pneumonia. Similarly, there may be little or no CSF pleocytosis even when bacteria are recovered from the

spinal fluid. In general, the inflammatory response parallels the maturity of the infant, the specificity of clinical signs and symptoms, and to some extent the prognosis. Late-onset infections, occurring beyond the immediate newborn period, often tend to be more localized and have a better outcome. Meningitis is common, but sepsis without meningitis is frequently seen. Bacteremia or meningitis may be associated with an infective focus, such as omphalitis, otitis media, or osteomyelitis. The long-term outcome of infants who survive group B streptococcal meningitis is generally good. Very occasionally, neonates develop similar disease due to group G streptococci or pneumococci. Maternal group B streptococcal disease may occur during gestation, notably urinary tract infections and septic abortion. Infection around the time of delivery, especially amnionitis, is a threat to both fetus and mother. Endometritis and bacteremia are the most frequent postpartum infections. Endocarditis is an unusual complication of perinatal infection or septic abortion.[162]

Group B streptococcal disease also occurs in adult men and nonpregnant women. In a recent survey of invasive group B infections metropolitan Atlanta hospitals clinical diagnoses included skin, soft tissue, or bone infections (36%), bacteremia without focus (30%), urosepsis (14%), pneumonia (9%), and peritonitis (7%).[142] Another excellent clinical series, which also included data on group A, C, F, and G streptococcal infections, found that the case mortality rate was 31% among adults with group B streptococcal bacteremia.[199] Two-third of all patients were over 50 years of age, 22% had primary bacteremia, 25% had underlying nonhematologic malignancies, and 19% had diabetes mellitus. At least 50% of the mortality due to group B streptococci now occurs in the age group >65 years, attributed mainly to pneumonia and bacteremia without an identified focus.[143]

There is good evidence that group C and G streptococci are a cause of endemic pharyngitis in adults in open populations.[200,201] Of the several streptococci falling into serologic group C, it appears that large-colony *Streptococcus equisimilis* is more likely to be associated with clinical disease than the tiny-colony *S. anginosis* ("*milleri*") group. The presence of these organisms must be determined by throat culture, because the rapid *Streptococcus* antigen detection kits are specific for group A streptococci.

9. Control and Prevention

9.1. General Preventive Measures

Personal hygiene, adequate nutrition and housing, health education, and access to medical care are all important factors in prevention of streptococcal diseases. Inspection of food and milk production and proper pasteurization of dairy products are taken for granted in most developed countries but remain problems in certain areas. Strict asepsis is required in surgical and obstetric procedures. Simple infection control measures, especially handwashing, must be continually encouraged, and attention must be paid to the health of hospital employees working in patient areas.

9.2. Antibiotics in Treatment and Prevention of Group A Streptococcal Disease

Primary prevention of acute rheumatic fever consists of identifying and treating persons with acute streptococcal pharyngitis.[30] Antibiotic therapy is aimed at eradicating streptococci from the respiratory tract. Shulman et al. have made the case over and again that penicillin remains the drug of choice for treatment of streptococcal pharyngitis.[110,202] Penicillin may be given as a single intramuscular injection of ("long-acting") benzathine penicillin or as a 10-day course of oral phenoxymethyl penicillin. Other oral penicillins, especially amoxicillin, are also effective but are more expensive and offer no advantage other than palatability. The older oral cephalosporins (cephalexin, cefaclor, cephradine, cefadroxil) are effective in a number of conventional 10-day dose regimens. Several newer cephalosporins (cefprozil, cefpodoxime, loracarbef) are equally effective; 5-day dose regimens are currently under investigation but will not be recommended without further evaluation. Erythromycin is a well-established alternative drug for penicillin-allergic patients, except in some areas where resistance may be a problem. Clindamycin is effective but has a small potential risk of pseudomembranous enterocolitis. Tetracyclines, sulfonamides, and chloramphenicol are not effective.

Spread of streptococci within populations has been an effective means of reducing exposure in households and institutional settings. Mass prophylaxis with benzathine penicillin has been used in some epidemic situations but is now chiefly confined to certain military populations[157] (see Section 5.9). Eradication of pharyngeal carriage of group A streptococci using oral antibiotic regimens has been attempted with varying degrees of success. Effective regimens include amoxicillin/clavulanate (Augmentin®) or clindamycin orally for 10 days.[203,204] Patients with symptomatic streptococcal sore throat may remain infectious for 24 h after the onset of therapy and should not return to work, school, or day care before completing a full 24 h of antibiotic therapy.[181]

Secondary prevention consists of the regular administration of antibiotic to persons who have had rheumatic fever in order to prevent subsequent group A infections that could

trigger recurrent attacks or exacerbate existing rheumatic heart disease.[30] Secondary prophylaxis is cost-effective, reduces the risk of recurrence, and in many patients allows for healing of valvular damage occurring in the initial attack. Long-acting intramuscular benzathine penicillin is usually given at intervals of 2–4 weeks, depending on local prevalence of rheumatic fever. Although dosing every 3 weeks may not provide adequate penicillin levels through the third week, this regime appears to be adequate in most situations and is often recommended.[205,206] Alternatively, oral penicillin may be given daily, but lack of compliance is a major problem. Patients unable to take penicillin may be given sulfadiazine or erythromycin. The duration of secondary prophylaxis is not certain but must be tailored to the individual. Patients with valvular rheumatic heart disease are given prolonged, even lifelong, prophylaxis. Those without cardiac involvement should have prophylaxis for at least 5 years and at least through age 18. Prophylaxis may be safely discontinued in young adults without carditis, provided that they have adequate medical follow-up and prompt culture and treatment of pharyngitis episodes.[207] Patients with rheumatic carditis as part of their initial attack are at greater risk for more serious carditis recurrences and should be given prophylaxis well into adulthood and perhaps for life.

Patients who have had isolated chorea as the only manifestation of rheumatic fever appear to be at much less risk for carditis during subsequent recurrences. Most authorities recommend that these patients receive prophylaxis until age 21 or for at least 5 years, whichever is longer. Some patients have a syndrome of poststreptococcal reactive arthritis without fulfilling Jones' criteria. A few such patients have had silent or delayed mitral insufficiency and later developed acute rheumatic fever.[208] It is therefore generally recommended that patients with poststreptococcal reactive arthritis receive prophylaxis for at least 1 year at which point it may be discontinued if no evidence of carditis develops.[30]

The prevention of acute glomerulonephritis by antibiotic therapy has not been convincingly demonstrated, and prophylaxis may not be practical in most patient populations. Prompt treatment of minor skin trauma and insect bites with topical antibiotic ointment has been shown to reduce the occurrence of streptococcal skin infections and could reduce the risk of subsequent nephritis.[209,210]

Although it is well known that group A streptococci can spread from infected patients to close contacts, available evidence does not support the routine administration of prophylactic antibiotics to close or household contacts of patients with streptococcal toxic shock or necrotizing fasciitis.[211]

9.3. Surgical Approaches to Recurrent Group A Streptococcal Disease

Tonsillectomy or tonsillectomy with adenoidectomy are frequently performed because of recurrent throat infections. Although children who have surgery experience fewer throat infections over the subsequent 2 years, the difference in rates compared to controls is not impressive. These findings were confirmed by Paradise et al. in a carefully controlled study with stringent entry criteria.[212] Surgical intervention was beneficial for severely affected children over at least 2 years following surgery. Nevertheless, a substantial proportion of those managed nonsurgically had relatively little throat infection during the period of study, and the actual reduction in group A streptococcal infection rates was small. Their results appeared to "justify but by no means to mandate the performance of tonsillectomy" in carefully selected children. Treatment should be individualized, and should be considered only for severely affected children. More clearly defined indications for surgical intervention include patients with peritonsillar abscess or severe obstructive symptoms.

9.4. Antibiotics in Treatment and Prevention of Endocarditis

Several national groups periodically issue detailed guideline for management of infective endocarditis.[108,213,214] The major organisms include viridans streptococci and *S. bovis*, *Abiotriphia* and *Granulicatella, S. pneumonia*, group A, B, C, and G streptococci, and *Enterococcus*. Dosage and duration of antibiotic therapy depend upon whether the offending organism is highly susceptible or relatively resistant to penicillin. Enterococci vary in susceptibility to penicillin and gentamicin, and some strains, especially among *E. faecium*, are resistant to vancomycin.

Guidelines for prevention of infective endocarditis have recently been revised by British and American cardiology, dental, and infectious disease organizations.[215,216] Whereas it used to be commonplace to administer antibiotics prior to dental procedures for patients with a wide range of heart valve disorders, now only few limited diagnoses are considered for prophylaxis. These include patients with prosthetic heart valves, patients with a prior history of endocarditis, and those with unrepaired congenital heart disease and those with residual defects, prosthetic materials or devices that inhibit endothelialization. It has been concluded that bacteremia resulting from daily activities is much more likely to cause endocarditis than bacteremia associated with dental procedures. Only an extremely small number of cases would be prevented even if prophylaxis were 100% effective.

Scientific data demonstrating the efficacy of prophylaxis is lacking, except for conditions associated with highest risks for adverse outcomes.

9.5. Intrapartum Chemoprophylaxis Against Group B Streptococcal Disease

The rates of early-onset group B streptococcal invasive disease have declined significantly following the implementation of various programs of maternal screening and administration of intrapartum antibiotics, as described in Section 5.1. The original 1996 guidelines, a compromise that used either maternal culture screening or maternal risk factors, resulted in a 65% decrease in early-onset cases. Subsequent population-based surveillance of the two different approaches found that culture-based programs were at least 50% more effective than risk-based programs.[134] This prompted a revision of the guidelines in 2002 by the CDC in cooperation with the American College of Obstetricians and Gynecologist (ACOG) and the American Academy of Pediatrics (AAP).[28] The new guidelines, outlined in Figure 4, is based on results of combined vaginal and rectal culture performed on women at 35–37 weeks of gestation. Further surveillance during 2002–2004 has confirmed that the rates of early-onset disease have declined an additional 31% since implementation of the new guidelines.[14] Several European countries and Australia have instituted similar guidelines, and Dutch investigators have recommended a shift from risk-based to screening-based programs.[136]

The 2002 guidelines call for using penicillin G as the first choice for intrapartum prophylaxis, with ampicillin or cefazolin as alternatives.[28] A potential problem with antibiotic use in this setting is the possibility of selecting organisms with increased antibiotic resistance. So far no group B streptococci have become penicillin resistant. There is, however, some increased frequency of resistance to clindamycin, which is used as an alternative for penicillin-allergic patients.[27] Resistance to ampicillin among nontarget organisms, such as *Escherichia coli*, parallels rates in other community-acquired infections and does not appear to be related directly to intrapartum prophylaxis. Nevertheless, the resistance patterns of other organisms causing neonatal sepsis should receive continued attention and surveillance.[28]

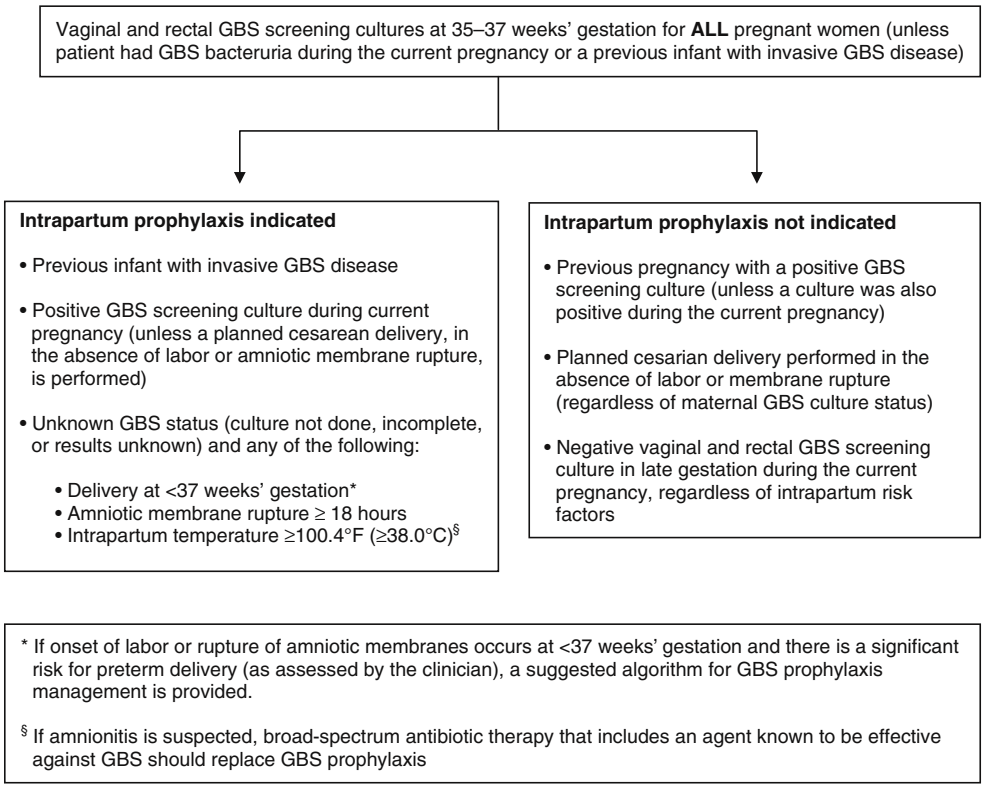
Prevention of neonatal infections by vaginal chlorhexidine disinfection during labor has also been investigated.[217] A reduction in transmission of group B streptococci from mother to infant has been demonstrated, but numbers have been too small to assess an effect of prevention of infections.[218] This approach might reduce the number of infection that develop as a result to colonization of infants during delivery, but as with intrapartum antibiotics, it should not be expected to affect infections that are already established in utero.

9.6. Passive Immune Prophylaxis Against Streptococcal Infections

The administration of gamma globulin has been employed for prevention of various bacterial infections in immunodeficient patients. The spectrum of host defense abnormalities that may benefit from this approach now includes patients with hypogammaglobulinemias, IgG subclass deficiencies, malignancy and immunosuppression, severe burns, bone marrow transplantation, and HIV infection.[219] Although passive immunotherapy was the only efficacious treatment for pneumococcal pneumonia in the years prior to the advent of antibiotics, no immunoglobulin products are in current use as adjunctive treatment for streptococcal infections.

9.7. Immunization Against Streptococcal Infections

A vaccine against rheumatic fever has been the holy grail of many investigators over the years. As reviewed by Bisno et al., current research involves two broad categories of vaccines: those based on type-specific M protein components and others containing virulence determinants that are common to all or many serotypes.[220] The M protein molecule is a coiled coil with three main antigenic regions: a nonhelical amino-terminus conferring type specificity and susceptible to antibody; the second area consists of B repeat subunits that cross-react with human tissue components; a third C repeat region has epitopes common to many M proteins; finally, the carboxy terminus ends with a cell wall spanning anchor region.[73] A multivalent recombinant M-type vaccine has now been constructed using the amino-terminal peptides of 26 of the clinically most important M types.[221] This vaccine has been tested for safety and immunogenicity in humans, and it elicits opsonizing antibodies to the respective M types. The vaccine does not contain any tissue cross-reactiveM epitopes from the B repeat area of the M protein and thus should not be able to provoke autoimmune-like responses. Other approaches to vaccines are promising but have not yet been studied in humans. A vaccine that contains epitopes of the carboxy-terminal C repeat area of the M protein cross-reacts with most of the common M types but also avoids the tissue-reactive B repeat area.[222] Another vaccine uses a lipid core as a carrier for the C repeat peptide, which has the advantage of not requiring a vaccine adjuvant.[223] A vaccine against the group A carbohydrate is



Vaginal and rectal GBS screening cultures at 35–37 weeks' gestation for ALL pregnant women (unless patient had GBS bacteruria during the current pregnancy or a previous infant with invasive GBS disease)
Intrapartum prophylaxis indicated
• Previous infant with invasive GBS disease
• Positive GBS screening culture during current pregnancy (unless a planned cesarean delivery, in the absence of labor or amniotic membrane rupture, is performed)
• Unknown GBS status (culture not done, incomplete, or results unknown) and any of the following:
• Delivery at <37 weeks' gestation*
• Amniotic membrane rupture ≥ 18 hours
• Intrapartum temperature ≥100.4°F (≥38.0°C)§
Intrapartum prophylaxis not indicated
• Previous pregnancy with a positive GBS screening culture (unless a culture was also positive during the current pregnancy)
• Planned cesarian delivery performed in the absence of labor or membrane rupture (regardless of maternal GBS culture status)
• Negative vaginal and rectal GBS screening culture in late gestation during the current pregnancy, regardless of intrapartum risk factors
* If onset of labor or rupture of amniotic membranes occurs at <37 weeks' gestation and there is a significant risk for preterm delivery (as assessed by the clinician), a suggested algorithm for GBS prophylaxis management is provided.
§ If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be effective against GBS should replace GBS prophylaxis

Figure 4. Indications for intrapartum antibiotic prophylaxis to prevent perinatal GBS disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures collected at 35- to 37-week gestation from all pregnant women. (From Centers for Disease Control and Prevention.[237])

enhanced by conjugation to tetanus toxoid to produce antibodies presumably protective against all strains.[76] A vaccine against the fibronectin-binding protein (FB54) targets a surface protein strongly associated with virulence.[224] Vaccines against the C5a peptidase of either group A or group B streptococci might not be directly protective but could reduce the effects of the more serious invasive infections.[225]

Group B streptococcal polysaccharide vaccines have been under investigation for over two decades.[226] Although intrapartum antibiotic prophylaxis has been fairly successful, it fails to prevent about 25% of early-onset infections and does not late-onset disease. Vaccines are projected to offer broader more cost-effective protection.[227] The goal of the vaccine approach is to immunize women in order to induce antibody that will later be capable of protecting the fetus against early-onset disease and perhaps afford protection for several months against late-onset disease. Ideally, a vaccine should induce antibodies of the IgG class to cross the placenta and be effective against all of the major serotypes. The first purified polysaccharide vaccine, against type III, was only modestly immunogenic. The immunogenicity was significantly improved by conjugation to tetanus toxoid, as was so successful with *Hemophilus influenzae* and pneumococcal vaccines. Phase I and phase 2 clinical trials have been successfully conducted with individual conjugates of types Ia, Ib, II, III, and V, and preclinical testing has been done with several multivalent vaccines.[226] Several surface proteins of known association with virulence are also being considered. These include several proteins common to nearly all strains, such as alpha, Sip, Rib, and the C5a peptidase, and the c protein, which occurs mainly with type Ia and Ib strains.[44,228] Assuming the eventual development of an appropriate vaccine, it will still be necessary to carefully define the target population. There is yet little enthusiasm for administering vaccines to pregnant women, mainly because of safety and liability issues.[229] It is possible that the target population would have to focus on or include nonpregnant women of childbearing age. The prospects for protecting the more premature fetus is uncertain, since only a minimal amount of maternally derived antibody is able to cross the placenta before the last trimester.[193] Nevertheless, it would be reasonable to suggest that any degree of protection afforded the mother would indirectly affect the fetus.

Pneumococcal vaccines have been studied for nearly 80 years. The 23-valent pneumococcal polysaccharide vaccine licensed in 1983 has been moderately successful in preventing invasive disease adults but has had little effect on nonbacteremic pneumonia.[230] A pediatric 7-valent conjugate vaccine (containing types 1 or 4, 6B, 9V, 14, 18C, 19F, and 23F) was introduced in the United States in 2000, resulting in a decrease of at least 60% in invasive pneumococcal disease among children less than 2 years of age.[170] Wide application of this vaccine has also benefited older adults by producing "herd immunity" and reducing spread.[171] However, nonvaccine serotypes are starting to creep into the population, including a particularly virulent 19A strain.[117] The need for a more universal pneumococcal vaccine is apparent. Several pneumococcal surface proteins, such as PspA, are currently being studied as candidate vaccine for humans.[103,231]

9.8. Prevention of Dental Caries

Conventional approaches to caries prevention have been succinctly reviewed in the Canadian Task on the Periodic Health Examination.[147] Primary prevention includes fluoride, fissure sealants, dietary counseling, oral hygiene, and identification and care of individuals at high risk of developing dental caries. Patients at greatest risk are those with bulimia, Sjögren's syndrome, chemotherapy, radiation therapy, or use of drugs that reduce saliva flow over long periods.

Fluoride-containing toothpastes afford considerable protection against dental caries and are the now most widely used method of providing fluoride. Fluoridation of drinking water at levels of 0.7–1.2 ppm remains an effective public health measure but is not without controversy. About two-thirds of the US population receive fluoridated water, compared to 40% in Canada, 10% in the United Kingdom and in Spain. France does not fluoridate, and Switzerland has replaced fluoridation with fluoride in domestic salt. Fluoride mouthwashes are probably of marginal value in communities with fluoridated water. They are not intended for children under 5 years of age, who may ingest excessive amounts and be in danger of fluorosis. Professional application of topical fluoride may be helpful for high-risk individuals and patients with active caries but is not currently recommended for routine use because of the overall decline in caries incidence.

Sealing of dental pits and fissures with synthetic resins has been done for over 15 years with modest success. Sealants do not add significant protection to initially sound tooth surfaces but may add to further reductions in caries where rates are already quite low.[146] This approach is recommended for selected high-risk patients whose permanent molars have erupted within the previous 2–3 years.[147]

Traditional brushing and flossing has little or no effect on caries prevention, except as a method of applying fluoride in the dentifrice. Professional cleaning (dental prophylaxis) does not prevent caries, although it may be useful for removing stains or calculus. The effectiveness of dietary counseling aimed at reducing intake of sucrose has not been established. Avoiding prolonged use of baby bottles and bedtime bottle propping may prevent "nursing caries." Nevertheless, it is now recognized that parental attitudes and beliefs play a key role in moderating oral health-related behavior in young children.[148]

Vaccines against dental caries, based on antigens derived from *S. mutans,* have been under investigation for a number of years.[184,232] Experimental vaccines have been successful in preventing caries in animals. Candidate vaccines include surface adhesins (Ag I/II, antigen B), glycosytransferases (GTF) that synthesize adhesive glucan from sucrose, and glucan-binding proteins. Several small clinical trials have demonstrated the feasibility of similar vaccines in humans. GTF vaccines given orally, intranasally, or topically applied to tonsils have been shown to induce salivary IgA antibody responses in humans, but long-term evaluations of efficacy have not been done. The major reason is that dental caries is not a life-threatening disease, and potential benefits must clearly outweigh even theoretical concerns of safety.

10. Unresolved Problems

Despite the availability of antibiotics, the diagnosis and treatment of group A streptococcal pharyngitis continue to pose problems for the clinician. The distinction between infection and carrier state is frequently blurred. The new rapid diagnostic tests make it possible to treat promptly and reduce clinical symptoms, but it is unlikely that changes in clinical practice have influenced the recent resurgence of acute rheumatic fever or of severe invasive streptococcal disease and toxic shock. Further study of epidemiologic factors, pathogenic mechanisms, and host response is clearly needed. Poststreptococcal reactive arthritis and its less certain relationship with cardiac sequelae continues to present a clinical dilemma for clinicians.[208] Group A streptococci, along with staphylococci, have been suggested as an etiology for Kawasaki disease, a vasculitis syndrome that occurs mainly in children. It is hypothesized that staphylococcal toxin TSST-1 or streptococcal exotoxins act as superantigens and cause aberrant amplification of certain T-cell lines implicated in the disease process.[233]

Group B streptococci remain the most common cause of serious bacterial disease in newborn infants in many western countries. Despite similar maternal colonization rates and

presumably similar risk of exposure, the disease is infrequent in some areas of Europe and Asia. The reasons for this are not clear but could be of considerable practical importance. Methods for intrapartum antibiotic prophylaxis have been established but remain to be implemented on a wide scale. Meanwhile, we still have little understanding of the local and systemic defense mechanisms required to prevent infection by this usually benign organism. Other streptococci, particularly oral and enteric species, are constant companions that cause disease only under specialized circumstances. It is not clear whether some of these organisms are in fact "virulent" in certain settings, or whether the disease is due mainly to predisposing conditions in the host. The question may be moot, but answers would help us direct attention to better ways of preventing nosocomial and opportunistic infections.

The unanswered questions apparent from the discussions in this chapter remain: how do streptococci cause disease, and why do some individuals become infected while others do not? Many pathogenic strains of group A *Streptococcus* have been sequenced and genes corresponding to virulence factors have been catalogued. However, the regulation of these genes has not been adequately investigated. In addition, major virulence factors, such as exotoxins, enzymes, M proteins and polysaccharide capsules, have been identified, but the pathophysiologic mechanisms by which they interact with the host remain uncertain and do not completely explain the disease processes. The determinants of colonization, the defenses of the host at the mucosal level, and the development of local and systemic immunity are not well understood. More needs to be learned to facilitate the development of effective vaccines and implement other preventive measures.

CHAPTER 36

Syphilis

Anne Rompalo and Willard Cates

1. Introduction

Few fields of medicine have been more carefully scrutinized by experts than syphilis.[1–4] Whether in economic, political, social, ethical, or epidemiologic arenas, syphilis has been the prototypic sexually transmitted disease (STD) control program of the 20th century.[4] Thus, the approaches taken and the measures used have been the model for control programs directed toward other STDs. In addition, many other clinical preventive services, such as those for tuberculosis, immunization, maternal and child health, and human immunodeficiency virus (HIV), have used concepts derived from syphilis control activities in their own prevention strategies. However, much of the epidemiological knowledge about syphilis control occurred prior to the 1950s.[4]

This chapter reviews the factors affecting syphilis epidemiology and control, including historical tradition, epidemiological bases, screening approaches, clinical management, and potential for immunization. It concludes with a consideration of future directions.

2. Historical Aspects

2.1. Early History

Syphilis carries a controversial history, not only because of its prurient nature but also due to its alleged origins. Two theories predominate. The unitarian theory holds that syphilis, like yaws, began in equatorial environments, being transmitted by casual contact. However, when the organism migrated to colder climates where more clothing was worn, sexual transmission provided the main avenue for contact with *Treponema pallidum*. The Columbian theory holds that syphilis arose in North America and was brought back to Europe around the beginning of the 16th century. It later received its current name from a poem written in 1530 about an infected shepherd called Syphilis.

History is replete with the names of illustrious individuals who may have contracted syphilis, but folklore implies a tenuous veracity.[5] Documentation of the symptoms and signs of the illnesses is usually poor, and specific diseases are not identified as such. Nonetheless, syphilis, like smallpox, produced measurable historical consequences. The fates of national armies, royal succession, and international explorations have all been affected.

The key discoveries involving syphilis occurred in Germany in the early 20th century. Within 10 years, the spirochete was identified (1905), the Wasserman reaction developed (1906), and Salvarsan discovered (1909). Knowledge in this field progressed rapidly with acceptance of the germ theory, development of serological tests, and the use of toxic cures. At the same time, the increasing professionalization of medicine coincided with the rise of venereology as an established specialty. Syphilis became the disease on which the skills of 20th-century physicians were judged.

2.2. Social Attitudes

Throughout history, syphilis has caused society to wrestle with moral issues associated with public health problems. Fortunately, in recent years, the human tragedies suffered by those with syphilis have led to more effective social and political responses designed to interrupt transmission and reduce complications, rather than to stigmatize those suffering from disease.[4]

During the past century, American society evolved toward a more tolerant view of those with syphilis.[4] Before

1900, physicians were known to withhold treatment for the illness, fatalistically regarding infection as evidence of (and even punishment for) promiscuous behavior. During the early 1900s, the "social hygiene" movement highlighted syphilis as a major public health problem; although illicit sexual forays were still scorned, at least the consequences of sexual intercourse could be both discussed publicly and treated professionally. Campaigns were waged against prostitution, and condoms were marketed as prophylaxis against infection (and pregnancy).

In the New Deal era, Surgeon General Thomas Parran seized an opportunity to dramatize the plight of those with syphilis.[1] With the availability of penicillin and the higher moral imperative of winning a world war, during the 1940s, the image of syphilis shed even more of its stigmatic cloak. Syphilis could be diagnosed and treated on an outpatient basis, thus allowing a more positive attitude toward finding and treating both patients and partners alike. During the most recent decades, the changing role of women and homosexuals in society was accompanied by a shift in the nation's attitude toward human sexuality. This created a growing constituency of those demanding personal and public health solutions, as well as an increasing sympathy for the "innocent victims" of the late sequelae. Thus, at the present time, social concerns about syphilis have a broad community base.[6]

2.3. Control Programs

In the United States, the first national syphilis control efforts began in 1918 when Congress passed the Chamberlain–Kahn Act, creating the Venereal Disease Division of the US Public Health Service.[4] Passage of this act was stimulated by World War I, when syphilis became recognized as a major cause for rejection from the armed services. However, the end of the war brought a decline of interest in the disease, and an effective national program never really began. Twenty years later, Parran's influence resulted in the passage of the National Venereal Disease Control Act, which provided annual grants-in-aid to individual states. This law established the basic model for federal, state, and local cooperation for venereal disease control efforts that remain in use today.[6]

During the 1940s, the primary objective of syphilis control programs was to prevent the late complications of the disease.[6] Public awareness programs set the stage for mass serological testing programs to detect infected individuals, who were then generally treated with heavy metals. Beginning in 1943, the so-called "Rapid Treatment Centers" were established by the federal government.[4] These inpatient facilities provided a course of 5- to 10-day arsenical therapy instead of the 70 weeks required on an outpatient basis. Soon thereafter, however, the availability of penicillin for widespread use contributed to making the syphilis control program even more successful. By the early 1950s, the reservoir of untreated or inadequately treated syphilis had been dramatically reduced. In succeeding years, the incidence of complications declined markedly. Over the next two decades, deaths attributable to syphilis decreased by 85%, and admissions to hospitals for syphilitic psychoses declined by 97%.[3] Congenital syphilis, for which somewhat better data are available, declined by 90% between 1941 and 1972.[7]

As the prevention of late complications became a reality, the interruption of syphilis transmission in its infectious stages emerged as the primary objective of control programs. The focus for public health officials shifted from lowering syphilis prevalence to reducing its incidence.[3] The strategy for accomplishing this has gradually evolved since the late 1950s. Building on the concept of case finding through routine blood testing, syphilis control programs increasingly emphasized case prevention by aggressive treatment of sex partners. Patients in the infectious stages of syphilis were interviewed to identify exposed sex partners, who were then offered treatment (termed "epidemiological treatment") before they could either develop symptoms and/or spread the infection. While this approach was successful in stemming outbreaks and reducing community levels of syphilis, it was costly in financial and human resources. Thus, syphilis control (like other public health programs) was vulnerable to the flow of financial support.

2.4. Funding Levels and Syphilis Incidence

State and local resources mainly support laboratory, diagnostic, and treatment services for syphilis. After adjusting for inflation, these nonfederal resources have remained relatively stable during the past 40 years. However, federal appropriations for STD control (not including HIV), which support the surveillance and outreach activities, have been more variable. From the high of over $17 million (absolute dollars) in 1949, resources decreased quickly to $13 million 1 year later, to $700,000 in 1955, when the availability of penicillin permitted the closing of the Rapid Treatment Centers and when sharp declines in early syphilis incidence suggested that the problem had been "solved."[3]

The optimism was ill founded; infectious syphilis increased in the late 1950s. A Surgeon General's Task Force considered the problem in 1961 and recommended a 10-year eradication program.[2] Federal grants to states for syphilis

control were increased from $2.4 million in 1960 to $6.3 million in 1965, and remained at this level until 1970. This effort was associated with a decline in syphilis incidence between 1965 and 1969. However, inflation led to sizable reductions in purchasing power, and infectious syphilis rates began to increase again in the 1970s.[7]

After 1970, resources for syphilis control were further eroded by the expanding spectrum of infections recognized as being sexually transmitted.[8] Although additional funds were appropriated for gonorrhea control in the 1970s and for chlamydia control in the 1980s, these new resources were never enough to support all the necessary STD control activities. Policymakers were forced to choose alternatives among secondary prevention approaches for the different organisms. Because of the greater burden of disease caused by gonorrhea, chlamydia, and viral STDs, syphilis was relegated to receive a smaller share of the STD resources during the 1970s and 1980s. In recent years, syphilis has received both an absolute and a proportional increase in federal STD funds.[8] In 1998, after a steady decline in incident syphilis rates to historic lows, a national plan to eliminate syphilis from the United States was initiated.

2.5. The National Plan to Eliminate Syphilis from the United States

The goal of the syphilis elimination effort at the national level was to reduce primary and secondary syphilis cases to 1,000 or fewer and to increase the number of syphilis-free counties to 90% by 2005. Five strategies were considered critical: enhanced surveillance, strengthened community involvement and partnerships, rapid outbreak response, expanded clinical and laboratory services, and enhanced health promotion. Between 1999 and 2004, CDC invested in excess of $107 million to high syphilis morbidity areas in the United States to support infrastructure, interventions, evaluation, research, community outreach, and clinical and laboratory services.[8]

Since the plan has been issued, declines in syphilis rates among key populations at risk have occurred. Between 1999 and 2004 primary and secondary syphilis rates decreased by 37% among blacks; the black–white racial disparity in syphilis rates fell from 28.6:1 to 5.6:1; rates among women overall fell 60%, from 2.0 to 0.8 cases per 100,000; congenital syphilis rates declined 39%, from 14.5 to 8.8 per 100,000 live births.[8]

Although the syphilis elimination effort has been extremely successful in decreasing syphilis among heterosexuals, since 1999 rates have been increasing among men who have sex with men (MSM). Sexual networks of MSM who are infected with syphilis are marked by high volume of sexual contact between the core and periphery. Infected MSM migrate across the United States, thus facilitating the introduction of infection into new susceptible subpopulations. The ability of MSM to identify sex partners over the Internet further complicates control strategies since the Internet facilitates anonymous sex and reduces the time required to form sexual links.[9]

The evolving epidemiology of syphilis in the United States, changing risk groups, and social environments present challenges for syphilis elimination program activities.[8] Syphilis is now diagnosed more frequently in the private as opposed to public sector, which raises concerns regarding rapid identification, reporting, and counseling as well as partner management. Public sector health services are currently facing increasing demands with decreasing financial resources. In response to this changing epidemic, the CDC has revised its broad syphilis elimination efforts and plans to target interventions to populations at greatest risk, and approve accountability of prevention efforts.[8]

3. Methodology

3.1. Sources of Mortality and Morbidity Data

Syphilis mortality estimates are derived from death certificates, as reported by the National Center for Health Statistics (NCHS). The accuracy of these data over time is influenced by changes in coding methods, diagnostic approaches, physician reporting candor, and autopsy percentages. Thus, the validity of mortality case definitions may vary over time, place, and patient population.

Syphilis morbidity data are collected by the Centers for Disease Control and Prevention (CDC) through formal surveillance systems based in the states. Data may vary in accuracy, depending on the priorities of STD control programs. These morbidity data tend to be more accurate in states that have laws that require reporting of positive syphilis serological tests.[3] Because private physicians are less reliable sources of morbidity data, the number of reported syphilis cases overrepresents patients seen in the public sector, and thus underestimates disease in the more affluent and older patient populations. Since public health partner notification activities are directed at interrupting infectious syphilis, morbidity of early syphilis is more accurate than late or latent disease.

Data on private sector case rates and disease sequelae can be derived from three annual sources: (1) the Hospital Discharge Survey of NCHS, which includes 7500 randomly selected hospitals from throughout the United States; (2) the

National Ambulatory Medical Care Survey of NCHS, which is a probability sampling of the diagnoses of 1900 physicians; and (3) the National Disease and Therapeutic Index (NDTI), which is a private survey of a random sample of office visits to US physicians in office-based practices. The major shortcoming of these databases is relatively small numbers of syphilis cases, which leads to wide confidence intervals in subpopulations.

3.2. Serological Surveys

Our syphilis seroepidemiological tools are inexpensive, relatively simple to perform, highly sensitive and specific, and readily available. Positive screening tests are generally followed by a variety of confirmatory tests to substantiate the diagnosis. Widespread serological testing is usually a poor case-finding tool for early infectious syphilis, but may be a good method for disease surveillance.

3.3. Laboratory Diagnosis

3.3.1. Identification of the Organism. In vitro culture of *T. pallidum* is not currently possible for diagnostic purposes. However, darkfield microscopic identification of the motile *T. pallidum* in secretions from primary, secondary, and early congenital lesions constitutes a rapid, reliable, and specific test. *Treponema pallidum* can also be identified from lesions and in biopsy material by commercially available direct fluorescent antibody (DFA) techniques. DFAs advantage is that the specimen can be transported to a laboratory where an experienced microscopist can make the proper identification. This procedure is ideally suited for testing oral and anorectal lesion secretions because it will differentiate *T. pallidum* from *T. denticola* and other spirochete strains.

False-negative darkfield and direct fluorescent antibody tests may occur even with adequate clinical specimens. Self-treatment with penicillin, for instance, can render a chancre darkfield-negative within hours. The same occurs when antiseptic ointments are locally applied to syphilis lesions.

3.3.2. Serology. Serological tests are valuable in syphilis diagnosis when ulcerative lesions are not available for darkfield examination. In primary syphilis, all serological tests are less sensitive than direct visualization of *T. pallidum*. When syphilis has reached the secondary stage, antibody levels have risen and nearly all serological tests are reactive.

Based on the character of the antigen, two major categories of syphilis serological tests exist. The first syphilis antigen is a defined combination of cardiolipin, cholesterol, and lecithin. These nontreponemal tests have similar sensitivities and specificities and include the Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR) tests.

The second category of syphilis serologies comprises the treponemal tests. Intact *T. pallidum* organisms are the antigens used in the *T. pallidum* immobilization (TPI) and fluorescent treponemal antibody absorption (FTA-ABS) tests. The TPI test is labor-intensive and is now used only in research laboratories. The *Treponema pallidum* particle agglutination assay (TPPA) is one of the newer confirmatory tests on the market. Recently the feasibility of using oral fluid as a specimen for TPPA testing was evaluated, but an approximate eightfold loss of assay sensitivity was noted when using oral fluid compared to serum for TPPA.[10]

False-positive nontreponemal tests are common and are usually of low titer ($\leq$1:4). False-positive nontreponemal tests are divided into acute and chronic, based on whether reactions revert to negative in less than 6 months. False-positive treponemal tests can also occur, usually associated with lupus erythematosus, pregnancy, and intravenous drug use.

4. Biological Characteristics of the Organism

Treponema pallidum is classified in the order Spirochaetales, genus *Treponema*. The latter includes both human pathogens and nonpathogenic organisms. The pathogens and the diseases they cause are as follows: *T. pallidum* (syphilis), *T. pertenue* (yaws), *T. carateum* (pinta), and *T. pallidum* variant (endemic syphilis). Morphologically, these four treponemes are identical. DNA homology has demonstrated a close similarity between *T. pallidum* and the other pathogens, but marked differences between the pathogens and the nonpathogenic treponemes.[11]

Cross-resistance between *T. pallidum* infection and the other treponemal infections suggests immunologic similarities. Syphilis nontreponemal and treponemal tests are reactive in patients with yaws, pinta, and endemic syphilis. Syphilis incidence is low in areas where yaws is endemic, but has increased after active yaws eradication program. The pathogenic treponemes can be differentiated by the host response in various animal models.

Treponema pallidum, like other treponemes, is a gram-negative bacterium. Its length varies from 6 to 15 μm, possibly because its reproductive cycle consists of growth in length followed by division half-way along its long axis. *Treponema pallidum* is a fragile organism, which is readily destroyed by disinfectants commonly used in laboratories and clinics. *Treponema pallidum* utilizes oxygen

and is microaerophilic. None of the human pathogenic treponemes have been grown in broth or on bacteriological media.

In 1998 the genome of *T. pallidum* was sequenced.[12] Its genome is relatively small suggesting that it utilizes hot biosynthesis to fulfill some of its metabolic needs.

While biological functions are suggested for only about 55% of *T. pallidum* 's 1041 open reading frames, even these relatively early studies offer important insights into syphilis pathogenesis. A family of repeat genes, the *Tp* genes, encode proteins homologous to the major sheath proteins of *T. denticola.* Antibodies to the *TprK* variable regions are protective in a rabbit model. With successive passage, increasing diversity is observed in the *TprK* V region genes. Antigenic variation through gene conversion has been hypothesized to be one mechanism of escaping immune surveillance, allowing for prolonged infection and persistence in the presence of a robust host response. Human and animal studies suggest that a Th1 response is elicited in primary syphilis. Progression to the secondary stage is accompanied by a shift to a Th2 response, allowing for incomplete clearance of the pathogen. In pregnancy, intense inflammatory responses and prostaglandins induced by fetal infection may be responsible for fetal death or pre-term delivery and severe growth retardation or other manifestations of congenital syphilis. Understanding of the molecular targets of these immune responses may facilitate the development of vaccines for syphilis.[13]

5. Descriptive Epidemiology

Because syphilis passes through both clinical and subclinical phases, case definition presents a dilemma for surveillance purposes. Trends in primary and secondary (P&S) syphilis provide a measure of disease incidence, since their symptomatic clinical presentations are of relatively short duration. This is especially true in men, where the chancre most often occurs on the external genitalia. In contrast, primary infections of women are reported less commonly. Latent disease rates, on the other hand, depend on the levels of screening and partner notification activities. Thus, trends in latent disease rates may reflect the levels of resources devoted to syphilis control activities.

5.1. Prevalence and Incidence

After the advent and widespread use of penicillin treatment, syphilis cases dropped dramatically.[7] Fifteen years after the introduction of penicillin, the number of syphilis cases had dropped by 90% (Figure 1). Cases reached their nadir in 1955. Thereafter, syphilis ebbed and flowed during the next 30 years as rates increased, then decreased in the gay male population. In the second half of the 1980s, heterosexual syphilis transmission was fueled by the crack-cocaine epidemic, and rates reached their highest levels since post-World War II. However, since 1991, P&S syphilis declined markedly; in 1994, just over 20,000 cases were reported, the lowest number since 1977.

Since 1999, substantial reductions in rates in women and newborn infants have occurred. Rates of P&S syphilis declined from 2.0 to 0.8 per 100,000 women. Rates in African-Americans fell from 14.3 to 8.9 per 100,000 population and the Black:White racial disparity was reduced from 28.6:1 to 5.6:1 (Figure 6). However, recent resurgence of syphilis among MSM has occurred since 1999 and in 2004, more than 60% of new diagnoses of P&S syphilis were estimated to occur in MSM, with HIV-positive MSM bearing a disproportionate burden of disease. Between 2004 and 2005, the national P&S syphilis rate increased by 11.1%, from 2.7 to 3.0 cases per 100,000 population, and the number of reported cases increased from 7,980 to 8,724. This increase has been reported for most age groups, for both sexes but more so among men, and for the second consecutive year the P&S rate has increased among blacks, with the largest increases among black men (from 13.9 per 100,000 in 2004 to 15.7 per 100,000 in 2005).

Congenital syphilis cases have paralleled the trends in female P&S disease (Figure 2). After 1988, the number of congenital syphilis cases increased dramatically, not only because of the rising incidence in women but also because of a broader case definition begun that year. However, because of the declining number of adult syphilis cases in the first half of the 1990s, congenital syphilis cases fell as well.[7,8] Between 1991 and 2004 congenital cases declined by 92% (107.3 cases per 100,000 live births to 8.8 cases per 100,000 live births).[8] Overall rates of congenital syphilis decreased by 12.1% between 2004 and 2005, from 9.1 to 8.0 per 100,000 live births.

5.2. Contagiousness

Except for intrauterine infection, syphilis is transmitted by sexual contact between infected and uninfected epithelial surfaces. The transmission rate is relatively high, especially after repeated exposures, and is inversely proportional to the stage of the disease. Among couples with frequent sexual contact, four out of five partners exposed to the infectious lesions of early syphilis were infected; less frequent transmission occurred when the index case had been infected for more than 4 years.[14,15] Among untreated nonconjugal sex

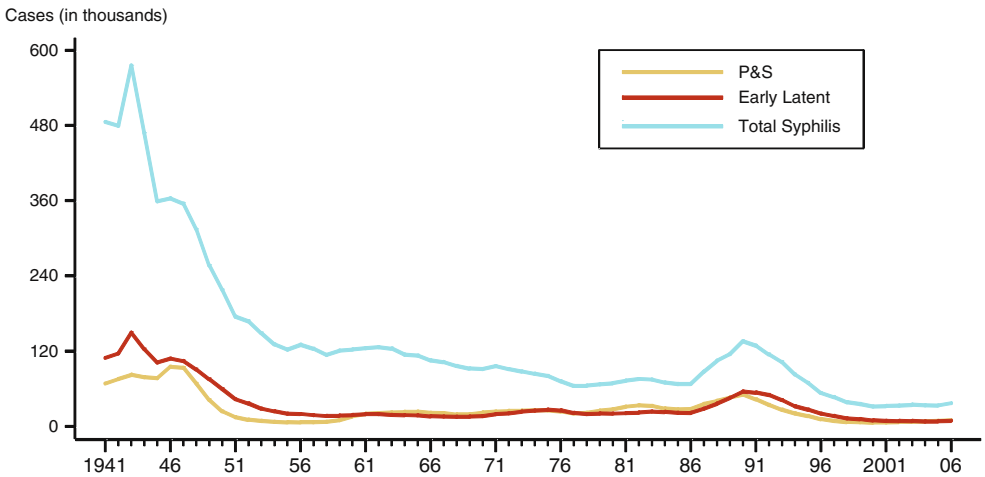

Figure 1. Syphilis – reported cases by stage of illness: United States, 1941–2006.

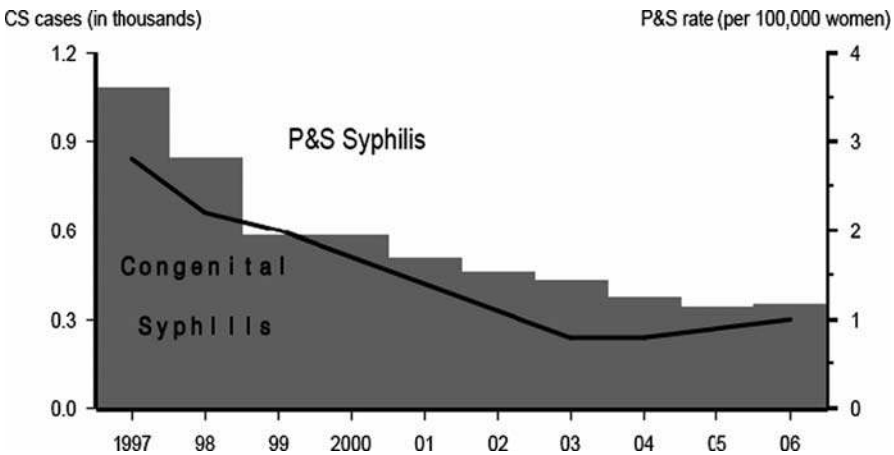

Figure 2. Congenital syphilis – reported cases in infants <1 year of age and rates of primary and secondary syphilis among women: United States, 1997–2006.

partners having less frequent exposure to patients with P&S syphilis, 30–40% acquired infection.[6,16]

The infectious dose for the transmission of *T. pallidum* infection is relatively low. The ID_{50} of the rabbit-acclimated Nichols strain for the production of intracutaneous infection in volunteers is about 50 organisms.[17]

Perinatal transmission of syphilis occurs as early as the ninth week of gestation.[14] The risk of intrauterine transmission of infection in maternal syphilis is high, and it varies with the stage of maternal disease. The risk of congenital syphilis acquisition is 50% in maternal P&S infections, 40% in early latent infections, and only 10% in late latent infection.[18] Healthy term infants were born to 10% of the early latent maternal infections and to 70% of those with late latent disease.

5.3. Geographic Distribution

Currently, the southern United States continues to have a higher rate of P&S syphilis than any other region. Cases in the South account nearly half of total P&S syphilis cases reported (Figure 3). Of 706 counties reporting at least one case of P&S syphilis in 2005, 5 (0.7%) had rates at or below the Healthy People 2010 target of 0.2 cases per 100,000 population. The 701 counties with rates above the Health People 2010 target accounted for 99.9% of the total P&S syphilis cases reported in 2005 (Figure 4).

5.4. Temporal Distribution

A seasonal trend pattern has not been demonstrated for syphilis.

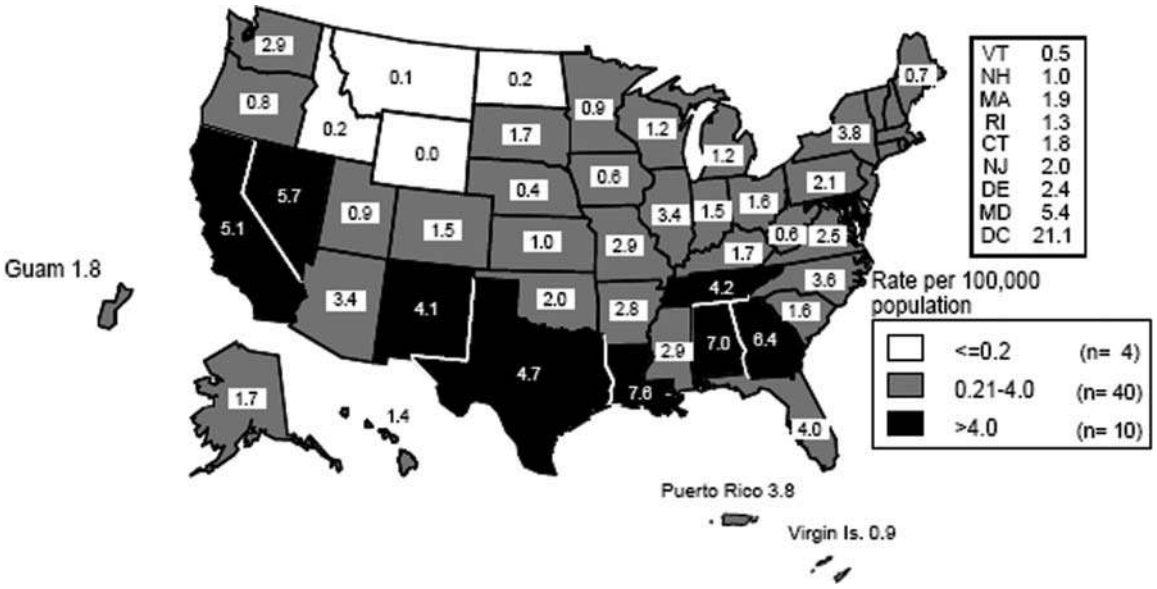

Figure 3. Primary and secondary syphilis – rates by State: United States, 2006.

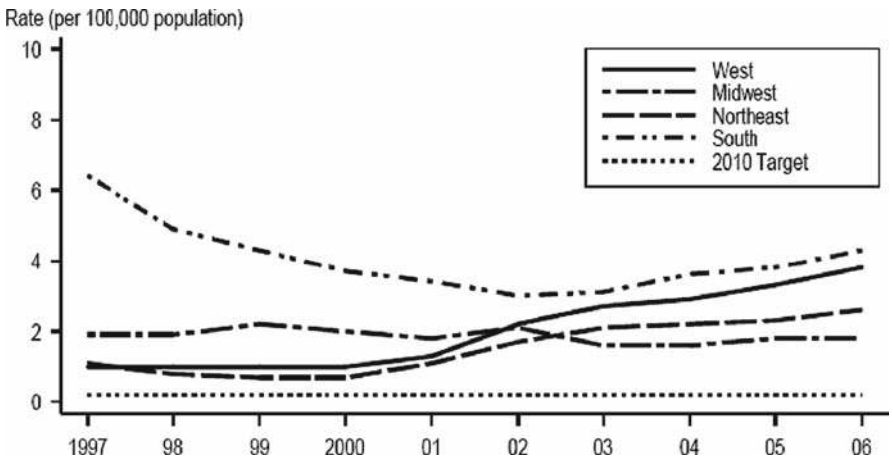

Figure 4. Primary and secondary syphilis – rates by Region: United States, 1997–2006 and the year 2010 objective.

5.5. Age and Gender

In 2005, the rate of P&S syphilis was highest among women in the 20- to 24-year-old age group (3.0 cases per 100,000 population) and among men in the 35- to 39-year-old age group (13.2 cases per 100,000 population) (Figure 5).

5.6. Race

Nearly all studies have found markedly higher syphilis case rates in African-Americans compared to whites. Recent trends showed African-American syphilis rates increasing markedly between 1985 and 1990, but declining precipitously thereafter, with a marked reduction in the Black:White ratio after the National Syphilis Elimination efforts began in 1999 (Figure 6). The reasons for the higher syphilis rates in African-Americans are currently not known. Racial and economic segregation help define sociosexual networks with an elevated prevalence of disease, thus maintaining high levels of infection.[19]

5.7. Occupation

With the exception of commercial sex workers, occupation bears no specific relationship to the risk of acquiring

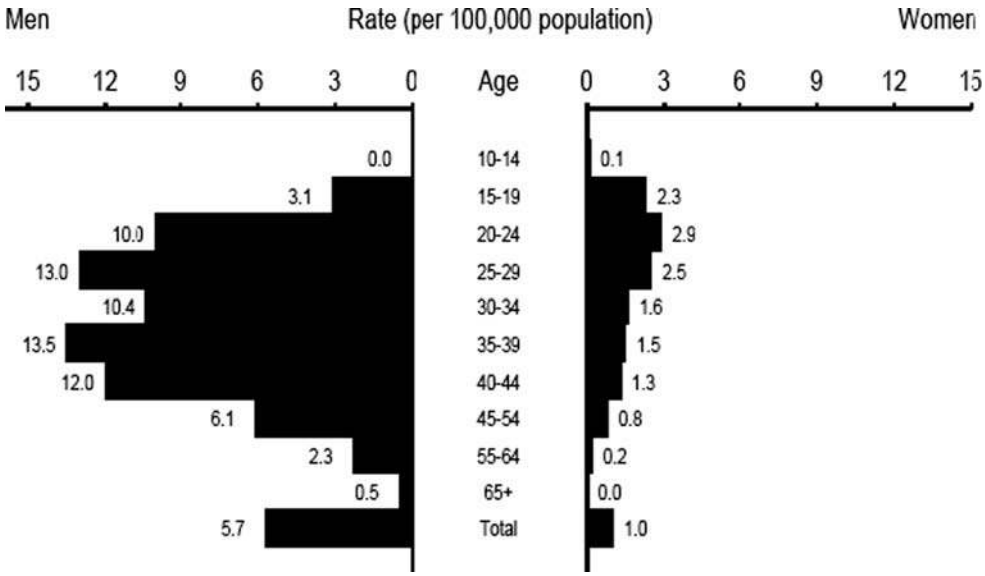

Figure 5. Primary and secondary syphilis – age- and gender-specific rates: United Stated, 2006.

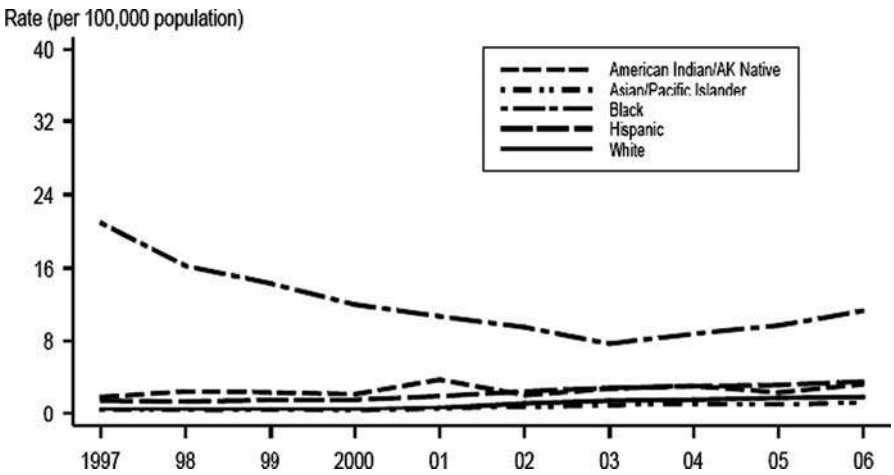

Figure 6. Primary and secondary syphilis – rates by race and ethnicity: United States, 1997–2006 and the year 2010 objective.

syphilis. Occupations that employ younger, sexually active individuals, especially from syphilis endemic areas, would likely yield higher infection rates.

5.8. Occurrence in High-Risk Environments

Over the past several decades, syphilis outbreaks have occurred in settings associated with high numbers of anonymous sex partners: the bathhouses serving gay males and crack houses serving low-income populations where sex is exchanged for drugs.

5.9. Socioeconomic Factors

While all social strata are at risk for sexually transmitted infections, syphilis has become entrenched in the poor.[19] Factors such as educational and income levels, which are directly related to the frequency of using prophylactic and therapeutic measures to prevent disease, are often important

determinants of the prevalence of syphilis and its transmission dynamics. Moreover, health-care seeking is also directly related to income level.

6. Mechanisms and Routes of Transmission

Treponema pallidum is transmitted during sexual contact between an infectious individual and a susceptible recipient. Infection of a sex partner occurs in about one-third of coital exposures. Initial infection fails to occur unless adequate numbers of treponemes are transferred to the partner's mucosa or abraded skin. No natural resistance was found in experimental infection of volunteers not previously exposed to *T. pallidum*.[17]

Infected individuals are not continually infectious to others. Patients may remain infected with *T. pallidum* from the time of inoculation until their death, but they are infectious to others primarily during the several weeks of the P&S stages of syphilis; late latent and late syphilis are not infectious stages.

For syphilis infection to be transmitted, adequate numbers of *T. pallidum* must be on the surface of the organ that contacts the recipient's skin or mucosae. The exact number needed to infect is unknown, but experimental intracutaneous injection of the agent required only 57 organisms.[17] *Treponema pallidum* can penetrate mucosal surfaces, but penetration is resisted by intact skin. It can penetrate through the skin abrasions that occur in sexual activity. Rabbits resist syphilis when *T. pallidum* is placed on normal skin, but the minimal trauma associated with shaving the animal allows the same skin to be infected.

In childbirth, a similar situation may occur when *T. pallidum* from a mother's genital chancre is transmitted to the child as it passes through the vagina. Under this circumstance, the chancre(s) in the newborn develops several weeks postpartum in the site(s) of birth trauma, such as where extraction forceps were applied to the head. The more common mode of congenital syphilis transmission is via a maternal septicemia with passage of *T. pallidum* through the placenta and into the developing fetus. Such a septicemia is most likely when the pregnant mother has primary or secondary syphilis. Treatment of an infectious mother in the first trimester may prevent congenital syphilis, because placental passage usually occurs during the second and third trimesters.

Hematogenous spread of *T. pallidum* has occurred with blood transfusions, but is quite rare. Treponemes are present in blood for only the short duration of the P&S phases. In addition, blood is screened with a syphilis serological test before it is transfused into a recipient. Fomite transmission of syphilis is virtually nonexistent, because *T. pallidum* is rapidly killed by drying. It has not been found in urine, milk, or sweat.

7. Pathogenesis and Immunity

Treponema pallidum infection evokes both humoral and cellular immune responses. The former's detection and quantification is important in the laboratory diagnosis of syphilis. Treponemal (anti-*T. pallidum*) and nontreponemal (anticardiolipin) antibodies begin developing in primary syphilis, and in the secondary stage all patients have high titers of both antibodies. Titers of anticardiolipin antibodies then start to slowly decline and spontaneously revert to negative in about one-third of untreated patients. Anti-*T. pallidum* antibodies remain detectable for the life of most patients. Cell-mediated immunity also develops in primary syphilis, appears to be suppressed during the secondary stage, and is again detected in the latent and late stages. The TPR K protein of the Tpr family of polymorphic multi-copy repeat proteins has been shown to be a target for opsonic antibody.[20]

The roles of antibodies and cellular immunity in resistance to infection are not completely understood. Human inoculation experiments have shown that syphilis infections confer some degree of resistance to reinfection.[17] Patients treated previously for primary or secondary syphilis were easily reinfected with *T. pallidum* despite having an anamnestic antibody response to both cardiolipin and *T. pallidum* antigens. Patients with untreated late latent syphilis were most resistant; many patients with this stage of syphilis resisted an intracutaneous challenge of 100,000 *T. pallidum*. This compares with an infectious dose of about 50 organisms for an initial syphilis infection. Resistance to reinfection correlated better with cellular immunity than with humoral antibodies.

Resistance to reinfection can be differentiated from chancre immunity. The latter is failure of *T. pallidum* to produce a second chancre while the primary chancre is still present. Chancre immunity may be secondary to cellular immunosuppression in early syphilis.

8. Patterns of Host Response

8.1. Clinical Features

The interval between infection with *T. pallidum* and development of the first clinical sign of syphilis varies from 10 to 90 days, with the typical case developing an ulcer (the primary chancre) in 3 weeks.[21] If someone exposed to

syphilis does not develop either a chancre or a positive cardiolipin serology within 90 days, he/she probably was not infected.

While clinical staging is imprecise, it provides a useful guide to treatment decisions and syphilis control activities. Considerable overlap between stages is common.[21]

8.1.1. Primary Stage. When infection does occur, the first sign of syphilis develops at the site of inoculation and consists of a pink to red macule. This flat lesion rapidly becomes a palpable nodule and within several days its surface erodes to produce the characteristic chancre. Chancres are usually single, without pain and are accompanied by painless regional lymphadenopathy. The asymptomatic character of such a large genital ulcer contrasts markedly with the pain of smaller genital herpes and chancroid ulcers.

A primary syphilis chancre heals spontaneously without treatment, usually within 2–3 weeks, but occasionally may persist for up to 8 weeks. A residual scar in the area of the chancre is rare unless the lesion was secondarily infected. The regional adenopathy requires a longer time to resolve spontaneously.

8.1.2. Secondary Stage. Several weeks after the chancre has healed, the manifestations of secondary syphilis emerge. Nonspecific symptoms of this stage include low-grade fever, headache, sore throat, malaise, anorexia, and arthralgias.[21] The most characteristic secondary syphilis signs, although not pathognomonic, are changes in the skin, hair, and mucous membranes.

Skin lesions are discrete and may be macular (flat) or papular (small palpable elevations), usually on the trunk, the palms, and the soles. Hair loss may occur in secondary syphilis. Patches of scalp hair are thinned rather than completely denuded and the result is a moth-eaten appearance to the scalp. In perineal sites, secondary syphilis lesions are generally nodular and are referred to as condylomata lata, similar to genital warts (condylomata acuminata).

A patient with secondary syphilis may have one, several, or all of the signs of the secondary stage. Since each of the signs may be associated with other diseases, none are specific to syphilis. However, when more of these signs are present, the diagnosis of syphilis is more likely to be accurate. The diagnosis of secondary syphilis is confirmed by the identification of *T. pallidum* in mucosal lesions or by the conversion of a syphilis serological test from negative to positive. Essentially all treponemal and nontreponemal syphilis serologies are reactive in this stage of syphilis.

The manifestations of secondary syphilis last 2–8 weeks and then, as with primary syphilis, heal spontaneously without residual scarring. When healing is complete, the patient enters into a latent phase with no clinical symptoms or signs of syphilis. The syphilis serological tests, however, remain positive.

8.1.3. Clinical (Infectious) Secondary Relapse. About 25% of untreated patients relapse from latency back into secondary syphilis.[22] This usually occurs during the first 5 years of latency, although most relapses take place in the first year. Such relapses are infrequent, possibly related to inadvertent syphilis treatment by systemic antibiotics used to treat another infection. The diagnosis of latent syphilis requires a spinal tap to differentiate it from asymptomatic neurosyphilis. The differential is important because neurosyphilis requires more prolonged therapy, as well as posttherapy spinal taps, to document therapeutic success.

8.1.4. Late Benign Syphilis. Late or tertiary syphilis occurs much less frequently today than was reported in the Oslo study of untreated syphilis.[8,22] As with the reduction in secondary syphilis relapses, this is probably related to inadvertent syphilis treatment when systemic antibiotics are used to treat a variety of other infectious diseases. This trend, however, may be reversing, since concurrent HIV infection may facilitate syphilis progression to symptomatic neurosyphilis.[23] This occurred in both untreated and treated syphilis patients.

One-third of untreated syphilis patients in the Oslo study progressed from the latent stage to one or more of the tertiary stages of syphilis.[22] The remaining two-thirds of syphilis patients remained asymptomatic during the rest of their lives. The sera of some of these asymptomatic patients also become nonreactive in the cardiolipin syphilis serological tests.

Three types of tertiary syphilis occur: gummas, cardiovascular syphilis, and central nervous system syphilis. Gummatous lesions developed in about 15% of the Oslo study patients.[22] These lesions have their onset 2–40 years after primary syphilis. Seventy percent of gummas involve the skin, 10% are found in bone, and a similar percentage are present on mucosal surfaces. Gummas can involve any organ. Skin and bone gummas are disfiguring, but involvement of a vital organ such as the heart or liver could be fatal.

8.1.5. Cardiovascular Syphilis. Cardiovascular tertiary syphilis develops 10–30 years after primary syphilis and was clinically evident in about 10% of the Oslo study's untreated syphilis patients.[22] Another 20–30% of untreated patients have cardiovascular changes that do not produce signs or symptoms. The microscopic pathology of cardiovascular syphilis is similar to that of neurosyphilis: blood vessel inflammation, which progresses to vessel occlusion. The vessels clinically involved in cardiovascular syphilis serve the aorta and the coronary vessels. Loss of this blood supply results in blood vessel wall death and scar formation.

Scar tissue within the aorta weakens its walls such that the aorta balloons outward, creating an aneurysm. Progression of syphilitic aortic valve damage eventuates in congestive heart failure and possible death. Incomplete syphilitic occlusion of the coronary vessels causes intermittent anginal cardiac chest pain. Myocardial infarction can occur when the coronary vessel occlusion is complete.

8.1.6. Neurosyphilis. Neurosyphilis develops 1–30 years after primary syphilis and involved 5–10% of Oslo's untreated patients.[22] The earliest form of symptomatic neurosyphilis, syphilitic meningitis, is also the least common (10% of neurosyphilis patients). It is manifest by typical meningitis symptoms: fever, headache, photophobia, and stiff neck. The spinal fluid findings are nonspecific—normal sugar and elevated lymphocytes and protein. However, a positive cerebrospinal fluid cardiolipin test differentiates neurosyphilis from other types of aseptic meningitis.

Later manifestations of neurosyphilis are due to blood vessel changes, which consist of vascular inflammation leading to vessel occlusion. The clinical manifestations of vascular neurosyphilis, as with other neurological diseases, depend on which areas of the brain are damaged. Strokes and seizures are early presentations of vascular neurosyphilis. Progression of vascular neurosyphilis consists of the involvement of more and more blood vessels with the subsequent loss of more brain tissue. The associated clinical state is referred to as paresis and is a combination of neurological and psychiatric changes. The latter is primarily a dementing process with loss of intellectual function, although some patients experience grandiose delusions. Common paresis neurological changes are eye pupil abnormalities (Argyll Robertson pupils), slurred speech, and tremors.

Spinal cord neurosyphilis consists of degeneration of the posterior columns. Nerve fibers in these columns transmit deep pain and proprioception sensations. Early clinical manifestations include transient (lasting minutes) sharp pains that radiate into the legs or abdomen. Loss of deep pain sensation in the legs results in repeated painless trauma to the knees and feet. The knees enlarge (Charcot's joints) and ulcers develop on the bottom of the feet (mal perforant).

8.2. Diagnosis

The clinical diagnosis of syphilis is based on its symptoms and signs.[21] The laboratory diagnosis of syphilis is based on visualization of *T. pallidum* and/or demonstration of antibody either to this pathogen or to cardiolipin antigen.

No single finding or test is in itself absolutely diagnostic of syphilis. The most accurate single diagnostic factor is usually the darkfield or direct fluorescent antibody demonstration of *T. pallidum*. The accuracy of these two tests, however, depends on how and where the clinical specimen was obtained, how it was transported to the laboratory, and who performed the test.

Treatment of syphilis is much easier than diagnosis. This infection was one of the first treated with penicillin in the mid-1940s. Unlike many other bacteria, *T. pallidum* has not developed resistance to this antibiotic despite penicillin's being the syphilis treatment of choice for a half-century. A single dose of 2.4 million units of long-acting benzathine penicillin G covers primary, secondary, and latent syphilis of less than 1-year duration. The same penicillin preparation in the same dose also treats both latent syphilis of more than 1-year duration and late syphilis; with these conditions, penicillin is given in three doses, 1 week apart, for a total of 7.2 million units. Some patients with late neurosyphilis do not respond adequately to this benzathine penicillin regimen and require hospitalization for 10 days for treatment with intravenous aqueous crystalline penicillin G or ceftriaxone 2 g given intravenously or intramuscularly daily for 10 days. Some experts give a singly 2.4 million unit dose of IM benzathine penicillin G at the end of the 10-day course to complete a 3-week course of therapy.

Syphilis occurring in pregnancy is treated with the same penicillin regimens. Nonpregnant patients allergic to penicillin can be treated with tetracycline or doxycycline. Pregnant patients with a history of penicillin allergy should have the allergy confirmed by skin tests. Those found not allergic can be treated with penicillin and those with positive skin tests can receive oral desensitization, followed by treatment with standard penicillin doses.

Syphilis treatment, like many other infectious diseases, requires follow-up to assure cure. In addition to resolution of the signs and symptoms of early syphilis, the cardiolipin serological tests should be repeated 6 and 12 months after treatment. A decline of at least two dilutions or a fourfold decline in test titers should occur after treatment, and most tests will revert to negative in cases of P&S syphilis. The anatomic damage occurring in late syphilis cannot be reversed, but treatment will prevent progression of the disease. Management of syphilis patients, as with other STDs, requires evaluation and treatment of sex partners.

9. Control and Prevention

9.1. Epidemiological Basis for Syphilis Control Activities

9.1.1. Transmission Dynamics. Many simultaneous activities are necessary to reduce syphilis, because of the

interactive behavioral and biological dynamics of syphilis spread. The forces responsible for sustaining transmission of any sexually transmitted infection, including syphilis, can be represented in a simple equation, $R = \beta \times C \times D$.[24,25] R represents the reproductive rate of an infection, i.e., the number of new infections produced by an infectious individual. β is the average probability that an infected individual will infect a susceptible partner given exposure. On average, without preventive measures, three of ten sexual encounters between an infectious and uninfected person[26–30] will result in transmission of syphilis (Table 1). C is the average number of new partners exposed by an infectious individual per unit of time. D is the average duration of infectiousness of the specific infection. Public health interventions to prevent syphilis are targeted at reducing the magnitude of β, C, or D by (1) reducing the probability of infecting a susceptible partner; (2) limiting the number of partners who have sex with infectious persons; and (3) reducing the duration of infectiousness.

Most current syphilis control activities emphasize reducing the duration of infectiousness. This approach rests on certain assumptions about the natural history of syphilis (Figure 7): for illustrative purposes, we will assume on the average that the moment of infection is followed by an incubation period of 3 weeks, by a 5-week period of primary syphilis, and by a 6-week period of secondary syphilis, after which the syphilitic infection becomes latent. The 11 weeks of P&S syphilis are considered the period of infectiousness.

Without preventive measures, three of ten sexual encounters between an infectious and an uninfected person will result in transmission of syphilis. Empirical data from national syphilis control programs[31] indicate that an untreated person with syphilis would generate, on average, 0.17 new infections per week during the 5 weeks of primary syphilis and 0.05 new infections per week during the 6 weeks of secondary syphilis, for a reproductive rate of 1.15 (Figure 7). At this level, in the absence of any effective intervention, the infection will propagate in the population. This hypothetical reproductive rate is a weighted average of rates from diverse subpopulations that lie on a spectrum from no transmission (reproductive rate less than 1) to intense transmission (reproductive rate of 2 or more). Although the reproductive rate of 1.15 is probably an underestimate, given slippage in the process of partner notification, it is of heuristic value in considering the impact of an intervention program.

Table 1. Risk of Infection in Persons Exposed to Infectious Syphilis, Selected Studies

Study	Number exposed	Number infected	Percent infected
Alexander et al.[26]	161	100	62.1
Idsoe et al.[27]	77	14	18.1
Moore et al.[28]	79	12	15.9
Schroeter et al.[29]	57	16	30.3
Schober et al.[30]	127	65	51.2

With a control program in which education, clinical diagnosis, and partner notification are effective, syphilis can be treated early in the course of illness and transmission can be interrupted (Figure 8). For example, community education can hopefully motivate infected persons to recognize symptoms of syphilis and seek medical care within 2 weeks after the onset of symptoms. Physicians in the community, if properly trained, can diagnose and treat the disease promptly. A system of partner notification seeks to assure the effective identification, referral, and treatment of persons exposed to infection. Under such circumstances, most of the partners of infectious persons will still be in the incubation period when treated, and the reproductive rate would be lowered to near zero. Such a theoretical goal is unlikely to be achieved. However, given our hypothetical reproductive rate of 1.15, even a 25% reduction in the number of infected partners per case per week during the primary period—from 0.17 to 0.13—would lower the reproductive rate to less than 1 and ultimately interrupt transmission within the community (Figure 8).

This model for controlling syphilis transmission is based on assumptions derived directly from the biological characteristics of *T. pallidum* and the clinical stages of the disease it produces. Compared to other STDs, *T. pallidum* has long division times and, as a consequence, an extended incubation period. Thus, with syphilis, we have a relatively prolonged opportunity to cure the infection before symptoms appear and the host becomes infectious. In addition, *T. pallidum* remains sensitive to long-acting benzathine penicillin. If the organism were to become resistant to this drug and require higher doses or more frequent administration of antibiotic therapy, syphilis control would be compromised. For these reasons, syphilis is a disease for which the interventions of partner notification and prophylactic therapy can have substantial impact. Other STDs with shorter incubation periods (e.g., gonorrhea) or less convenient therapies (e.g., chlamydia) should not be expected to respond as dramatically to control programs as syphilis.[32]

9.1.2. Core Populations. These interventions can be concentrated to achieve maximal impact. Community variability in syphilis reproductive rates will dictate the different levels of public health effort required. Over the past two decades, the heterogeneous distribution of all STDs, including syphilis, has led to the concept of "core populations."[32,33] Core populations (also called "epidemic networks") are defined as those sociosexual networks that contribute a disproportionate share to sustaining STD rates

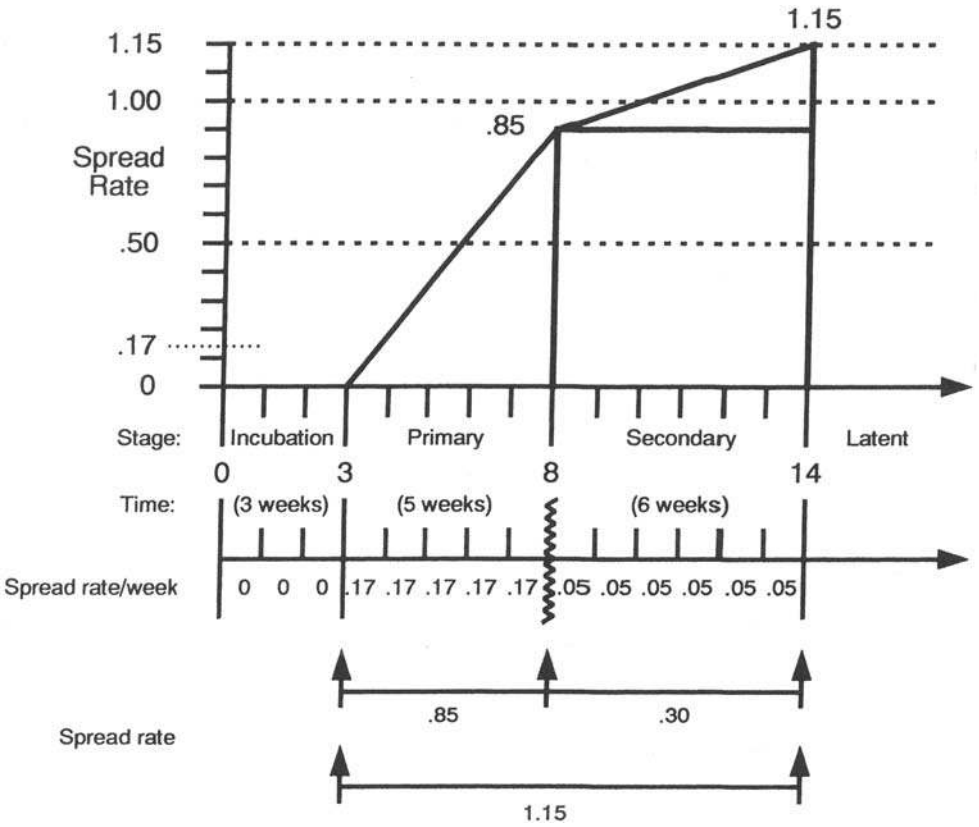

Figure 7. Projected reproductive rate of syphilis.

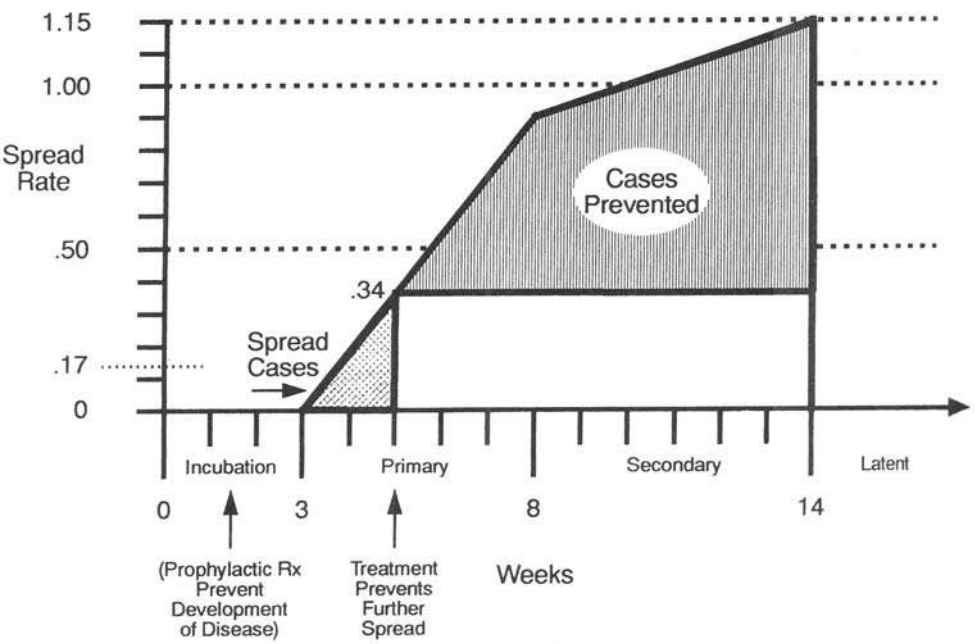

Figure 8. Preventing syphilis by treatment.

in communities. From the above model, as well as empiric data,[27] syphilis core groups will need higher rates of sex partner change than other STDs to maintain the infection within a sexual network.

Evidence supports this epidemic network concept for syphilis. In Seville, Spain,[34] syphilis (along with gonorrhea and chlamydia) showed a distinct spatial clustering. In upstate New York,[35] the distribution of syphilis was more diverse than gonorrhea, but still could be connected through two endemic foci: (1) inner-city, heterosexual African-American populations and (2) suburban, homosexual/bisexual white and African-American groups. In Multnomah County, Oregon,[36] a syphilis core population was identified using geographic and sociodemographic measures as proxies for these sociosexual networks. The Oregon core group, like others, was characterized by spatial clustering, low socioeconomic status, and a high proportion of African-American persons. In British Columbia, Canada, street nurses successfully used social networking approaches, environmental observation, peer outreach, serial interviewing, testing, and treatment in the field to increase the proportion of syphilis cases identified in a recent heterosexual outbreak.[37]

9.2. Control and Prevention

A recurrent theme in the control and prevention of syphilis is the need for a multidisciplinary coordinated, multifocal program. A variety of interventions, tailored to local epidemiological and social circumstances, are required to reach the epidemic networks and to lower the reproductive rate. The following sections summarize the chief elements of a coherent syphilis control program.

9.2.1. Screening. The advent of serological detection methods provided the technological impetus for modern syphilis control programs. Widespread testing to eliminate syphilis has enormous intuitive appeal. Nonetheless, the zeal for mass screening has been tempered by realistic comparisons of screening costs.[38] Such considerations have produced general agreement that universal syphilis screening in many industrialized nations, including the United States, cannot be justified.

Less unanimity exists, however, about the value of more targeted screening. First, attitudes toward syphilis screening change drastically with the slope of the trend line. The subjective valuation of screening a particular population will change if that community's perceived risk of transmission is thought to be high (e.g., the epidemiological importance of screening commercial sex workers). Second, confusion exists between the role of screening as a tool for case finding and the role of screening in interrupting transmission. Case finding generally rests on a subjective judgment of the social value of finding an infected person (e.g., the use of universal prenatal screening to detect the rare case of congenital syphilis). The interruption of transmission through syphilis screening is harder to verify primarily because detection of asymptomatic cases cannot be directly equated with diminished disease transmission. Except in situations in which syphilis incidence is increasing, most screening programs will identify persons in noninfectious stages of the disease, and thus will have little impact on transmission.

As described previously, the concept of screening in "core populations" has become increasingly popular. Whether these groups are defined by occupation (e.g., commercial sex workers), by facility (e.g., prisons, hospital emergency rooms), by risk environment (e.g., gay bathhouse, "crack house"), by geographic location (e.g., census tract), or by sociodemographic variables (e.g., poverty, ethnicity), the epidemiological principle is the same. Screening targeted to high prevalence areas should interrupt core transmission and should have an accelerated impact on reducing community incidence. This approach has been evaluated in Oregon, using geographic and sociodemographic markers for the core.[36] The results of this screening intervention were inconclusive; new cases were identified, but their connection to true core transmitters was unclear.

No incontrovertible guidance emerges from the literature on experience with syphilis screening. Despite the development of better quantitative tools for evaluation of costs and benefits, considerable subjective judgment is still required. Only one published report directly addressed the question of whether or not screening interrupts transmission of syphilis,[39] though the size and scope of that study may not have been sufficient to warrant generalization. Most studies discuss the "yield" of active syphilis cases; even similar syphilis yields evoke markedly different value judgments regarding public health utility.

Nevertheless, the diversity of screening data (and opinions) suggests two common themes. First, wide variation in the prevalence of syphilis provides a justification for screening as a form of cross-sectional syphilis surveillance. Second, the observed variation in syphilis positivity means that screening decisions should be based on local data—whatever criterion for efficacy is invoked. If screening is to have any value as a mechanism for case finding or for disease control, it must be locally applied and locally analyzed.

9.2.2. Clinical Diagnosis as a Tool for Disease Control. Syphilis symptoms and signs are protean. Clinical diagnosis, while difficult, is crucial for both case finding and prevention. Moreover, clinical services are the final

common pathway through which treatment is given, cure is achieved, and prevention is accelerated. Thus, these services must be easily accessible to the core populations.

Few studies have documented either the percentage of infected patients who recognize their syphilis symptoms or the percentage of those with recognized symptoms who seek medical services. Without such recognition and health-care seeking, opportunities for clinical diagnosis are diminished. In one nationwide study, 45% of persons who were identified through partner notification efforts admitted that they had recognized symptoms of syphilis but did not seek medical advice.[3]

Despite these difficulties, the majority of early syphilis cases reported to public health authorities have resulted from clinical diagnoses based on patient symptoms. In the late 1940s, about two-thirds of all persons diagnosed with primary or secondary syphilis sought medical care on their own initiative.[40] Likewise, in 1990, 62% of those with early syphilis obtained clinical services based on their own suspicions of illness (CDC, Division of STD/HIV Prevention, unpublished data, July 1991).

Even when the symptoms of genital ulcers occur and the patient seeks care, diagnosis using clinical parameters alone is notoriously difficult. This situation is made even worse when low prevalence leads to clinician unfamiliarity. For example, in one series of 100 patients with genital ulcers, clinicians without benefit of laboratory findings were unable to identify the specific microbial etiology more than half the time.[40]

The current evolving epidemiology of incident syphilis, changing risk groups, and social environments present challenges for elimination and STD program activities. Syphilis is increasingly diagnosed in the private sector, and concerns regarding immediate recognition of incident infection, as well as case reporting, are increasing. Public health services face increasing pressures from increasing demand and decreasing financial resources. The social contexts of poverty, homophobia, racism, and socioeconomic discrimination continue to drive the concentration of syphilis in those with high-risk sexual behaviors, poor access to care, or both.[8]

9.2.3. The Role of Treatment. Providing proper treatment for both symptomatic and asymptomatic persons is the sine qua non of syphilis control. Penicillin treatment based on presumptive diagnosis of syphilis is inexpensive, simple, safe, and effective. Thus, as shown on the model above, early and adequate treatment of syphilis patients and their sex partners is the essential means of preventing community spread.

In addition to treating those diagnosed with syphilis, selective prophylactic (preventive or epidemiological) treatment also has a major role in syphilis control strategies.[41] Over the years, this approach of selective preventive treatment has helped to limit multiple outbreaks of syphilis. Coupled with the process of active partner notification (see Section 9.2.4), prophylactic treatment of persons exposed to infectious syphilis has effectively controlled epidemics in both rural[42] and urban[43] settings. Benzathine penicillin for syphilis is especially helpful for outbreaks. Because it produces treponemicidal concentrations of penicillin for at least 3 weeks, this agent provides an interval of "antibiotic" quarantine[44] during which reinfection is hindered.

Within certain circumscribed communities with a high prevalence of infection, selective mass penicillin treatment has been useful. For example, in Fresno, California, in 1977, selective mass treatment of commercial sex workers interrupted an ongoing syphilis epidemic.[40] The same strategy, though for different indications, has been applied by the World Health Organization for eradicating yaws.[45,46] Not surprisingly, this mass treatment approach also lowered the prevalence, albeit temporarily, of venereal syphilis in those communities where it was applied.

Azithromycin, 2 g in an oral single dose, would be an ideal alternative to the penicillin injection, since it could easily be given in field settings. It has been reported as effective as the IM penicillin therapy in a treatment trial conducted in Mbeya, Tanzania.[47] However, recent reports of azithromycin-resistant *T. pallidum* in the United States, Ireland,[48] and Canada[49] indicate the importance of continued monitoring for resistance.

9.2.4. Partner Notification. Rapid investigation of sex partners is aimed at bringing persons with early syphilis to treatment before they can spread the infection within the community. In fact, syphilis is the prototypic STD on which the prevention strategy of partner notification was based, both in theoretical concept and in practical application.

Traditionally, syphilis control programs in the developed countries have emphasized active intervention by health providers to interview patients, to identify sex partners, and to assure that partners are evaluated and treated.[50] The privacy of patients and partners is rigorously protected. Up through the 1960s, a number of reports attested to the success of this epidemiological approach for syphilis control.[28,51–55] Whether applied to isolated rural communities,[56,57] selected urban neighborhoods,[58] or captive prison settings,[50] rapid sex partner identification, location, and treatment reduced syphilis occurrence.

The partner notification process involves a series of interrelated activities: interviewing the infected patient to obtain a complete list of exposed sex partners, finding these

persons in the community, and assuring that they are treated promptly. In the United States, interviewing techniques have been developed to encourage patient cooperation in naming a maximum number of partners.[3] However, during the 1960s and 1970s, the contact index—a measure of the yield of the syphilis interview—steadily declined (Figure 9). Possible interactive reasons for this trend include a true decrease in the number of sex partners in infected persons; changing environments for sexual relations whereby a greater percentage of partners are anonymous (e.g., gay bathhouses, crack houses); an increasing atmosphere of distrust of all governmental organizations, including those delivering public health services; deteriorating interviewing techniques; and the increasing competition for partner notification services of other STDs.

Using specific populations, rather than infected individuals, as the units for syphilis intervention is a means for overcoming problems with naming and locating sex partners. In the past, this community-oriented approach was a type of "cluster" interviewing. Syphilis patients, in addition to their known sex partners, were queried about other persons in whom and specific social settings in which syphilis transmission may have occurred.[60] Although this cluster approach produced a lower yield of infected, previously untreated patients than following up those specifically named as sex partners, it still identified a relatively high percentage of persons who might not have been reached in any other way. In fact, depending on how the "socially related group" was defined, up to one in five people examined had untreated syphilis.[60]

In recent years, similar population-based approaches have been used to identify particular communities at high risk of syphilis. Examples of situations in which this community intervention was successful in stemming syphilis outbreaks include (1) a Native American tribe reluctant to name any partners to outside officials,[61] (2) a Philadelphia neighborhood where crack-cocaine environments led to unsafe sexual behaviors and high levels of syphilis,[62] and (3) a Montgomery County, Alabama, intensive program that identified sociosexual networks responsible for the continued spread of syphilis.[63]

The Internet is a rapidly growing venue for the acquisition of sex partners.[64] Recent published reports describe the use of the Internet by MSM to meet multiple casual sex partners and partners of unknown HIV status. This is a growing public health concern since some Internet users with syphilis report unprotected anal intercourse, and have difficulty identifying partners or have anonymous partners. Consequently, public health officials are developing strategies to use the Internet to reduce transmission of syphilis and other STDs by

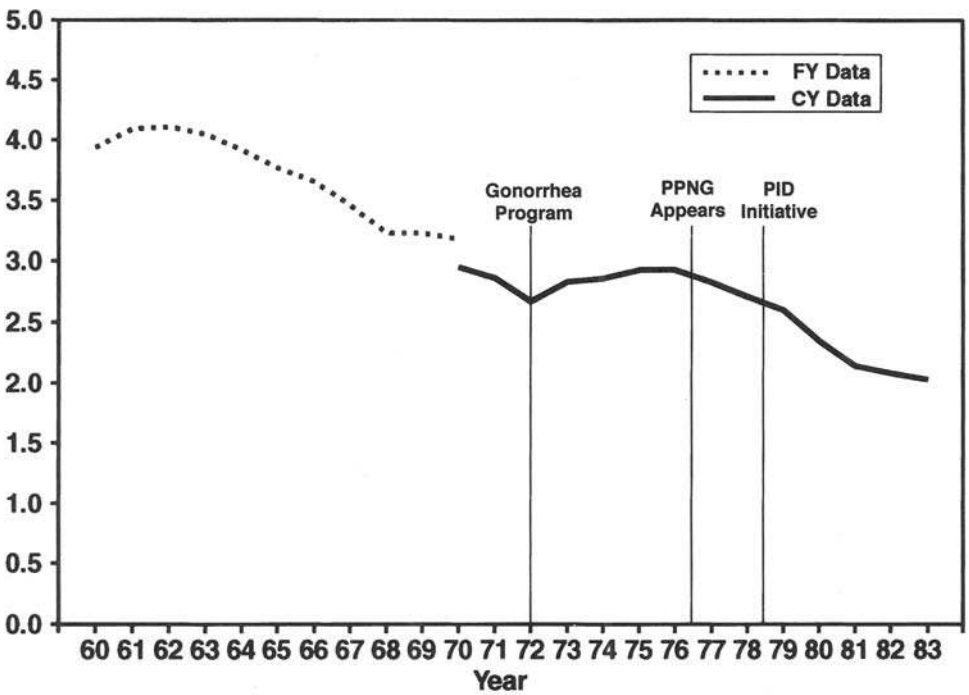

Figure 9. Contact index, 1960–1983, primary and secondary syphilis, public STD clinic patients.

notifying partners through screen names,[64] providing health education and prevention messages on Web sites via pop-up ads and links to Web sites that offer information on STD testing sites, making health education available in chat rooms to answer health-related questions, and offering online test result reporting.[65]

9.2.5. Health Education. Our current community health education efforts usually encourage primary prevention (preventing acquisition of syphilis) in persons at risk. Over the last two decades, HIV prevention resources have stimulated community education for safer sexual behaviors, which in turn has led to safer social norms. Health education interventions can also be directed to individual patients diagnosed with syphilis. They are designed to promote early therapy if symptoms such as genital ulcers recur, avoidance of sex after onset of syphilis symptoms, and notification of all sex partners. If successful, this counseling will result in both primary prevention (prevention of further syphilis transmission) and secondary prevention (prevention of later complications).

Other primary prevention approaches, financed by HIV prevention dollars, could also help reduce syphilis. These include both advocating risk avoidance methods and distributing condoms and counseling about safer sex. Condoms, although shown to be effective in limiting the transmission of HIV and other STDs,[66] are not used regularly by many high-risk individuals. Thus, we need more creative methods of condom promotion, including making them more widely available at little or no cost, to enhance syphilis control. However, sexual behavior change is not easily achieved in populations characterized by drug use, poverty, low education, unemployment, and inadequate health care. These groups need to be specifically targeted by health education campaigns and provided improved access to health care for syphilis screening, diagnosis, and treatment.[67]

Experience with HIV community education has shown that (1) changing social norms is fundamental to influencing safer individual sexual behavior and (2) reinforcing these safer behaviors regularly by trusted peers is crucial to preventing relapse to unsafe practices. Syphilis control in the homosexual community has already benefited from these HIV lessons. In socially disadvantaged communities, pilot programs using commercial sex workers as outreach workers have been successful in educating high-risk women about syphilis and in identifying pregnant women who need prenatal care, including syphilis testing.

9.2.6. Immunization. Another hope for primary prevention of syphilis is active immunization against either the infection or the disease. Because of the immune response generated during the natural history of untreated *T. pallidum* infection, prospects for developing a protective vaccine might seem encouraging. Acquired resistance to further *T. pallidum* infection occurs from both human and experimental syphilis.[68] However, attempts to generate long-term protection using a single immunogen have been disappointing.[69] With genome libraries and sequence now available, we might explore the rare *T. pallidum* outer membrane proteins, which are the first targets of the immune response. Their discovery and use in a multivalent vaccine may lead to the production of an effective vaccine for the future.[70]

10. Unresolved Problems

1. *More accessible clinical services*: All symptomatic patients must be able to receive prompt diagnosis and treatment. If public or private facilities are not available or are overburdened in the high-incidence communities, then temporary, mobile alternatives must be provided.
2. *Population-based partner notification*: Data obtained from the process of eliciting the location and sociosexual networks of sex partners must be used for both individual and population benefits. Where epidemiological analysis of partner patterns reveals high-risk communities, public health officials must move quickly to intervene clinically.
3. *Wider prophylactic treatment*: Among selected population for which levels of infectious syphilis are high, prophylactic treatment based on "epidemiological" indications must be considered. Alternatively, targeted community screening, with immediate presumptive treatment of all rapid plasma reagin-positive patients, must be implemented.
4. *Greater community involvement in syphilis control*: Public health officials must continue to build on the network of community-based organizations generated by interest in HIV prevention. Local decision makers must be reeducated about the importance of syphilis and the role of early diagnosis/treatment in preventing its spread, so they can become advocates for promoting behavioral change and securing clinical resources.
5. *Ongoing provider training*: Clinicians must be trained to "think syphilis," especially if practicing in high-incidence communities. Residency programs should include rotations through local STD clinics, not only to upgrade clinical STD skills but also to allow an understanding of real-world behaviors contributing to syphilis spread.

In actuality, these challenges are really nothing new.[6] "Environmental" or "community-based" approaches to controlling syphilis have long been with us. In multiple situations during the past four decades, after intensive screening programs documented high levels of syphilis in particular sociosexual networks, the "risk marker" of being in that network became enough of an epidemiological justification to "presumptively treat" persons for syphilis.[6] Not surprisingly, the morbidity level in the community was drastically lowered.

Are we simply suggesting reinventing the wheel? In one sense, yes; in another sense, no. Bolstered by our rapidly evolving electronic data system, we are better able today to target interventions, design appropriate evaluations, and disseminate the results of our efforts than we were in earlier years. Working together, epidemiologists (clinical, behavioral, and statistical) and program managers need to merge their skills both to document the success of specific syphilis control activities and to refine those that are less effective. This epidemiological/managerial interaction to continually evaluate our interventions will keep syphilis control at the cutting edge of public health well throughout the 21st century.[6,8]

CHAPTER 37

Nonvenereal Treponematoses

Ammar M. Ahmed, Vandana Madkan, Julie S. Brantley, Natalia Mendoza, and Stephen K. Tyring

1. Introduction

The endemic treponematoses are a group of chronic diseases affecting primarily the skin of children and young adults who live in remote, impoverished areas between the tropics of Cancer and Capricorn. They are considered as a group because they have many clinical, pathological, and epidemiological features in common (see Table 1). They are also caused by spirochetes that are closely related to one another and to *Treponema pallidum* subsp. *pallidum* of venereal syphilis.[1] These diseases with their etiologic treponeme in order of their worldwide prevalence are yaws (*T. pallidum* subsp. *pertenue*), endemic syphilis (*T. pallidum* subsp. *endemicum*), and pinta (*Treponema carateum*).[2] Other related treponemes cause venereal syphilis in rabbits (*Treponema cuniculi*) and asymptomatic infections in African baboons (*Treponema freiborgblanc*), but they have no epidemiological significance as far as human infections are concerned.

2. Historical Background

The endemic treponematoses are ancient diseases. Yaws, for example, is thought to have its origins in Africa during the middle Pleistocene period (1.5 million years ago), with characteristic bony lesions having been found in skeletal remains of *Homo erectus* in Nairobi.[3] There is an ongoing debate about the origins of the treponematoses. In the early 1960s Hudson and Hackett proposed competing theories. Hudson argued that the causative organisms were genetically identical, and that the differing clinical manifestations were solely due to the distinct climates of endemic regions.[4] Hackett's position was that while closely related, the organisms were genetically distinct, and that this would account for different disease manifestations.[5] The latter position seems to be the more tenable given the organisms' distinct growth characteristics in experimental animals,[6] lack of complete cross-immunity across subspecies (as evidenced in the rabbit model),[7, 8] and recently discovered genetic differences between *T. pallidum* subsp. *pallidum* and the nonvenereal subspecies.[9–11]

Until the last few decades the endemic treponematoses were a major cause of morbidity in developing nations, and yaws in particular was one of the most prevalent infectious diseases of the tropics before the penicillin era. In 1950, an estimated 70–100 million people living in large areas of Africa and Southeast Asia, the western Pacific islands, and parts of the Americas had yaws; another 1 million living in the Middle East, the Balkans, and North and West Africa had endemic syphilis; and 700,000, primarily American Indians of Central and South America, had pinta (see Figure 1).[12] The ratio of infectious to latent yaws was 1:3 or more, and most infections occurred in children under 15 years of age.

The first drugs used effectively against the endemic treponematoses (and venereal syphilis) were not penicillins, but rather arsenical compounds, discovered in 1910. In the 1920s and 1930s many developing countries organized yaws treatment campaigns using multiple injections of arsenicals at hospitals and by mobile units and rural dispensaries, with resounding clinical success.[6] These early yaws campaigns were a launching point in the development of primary national healthcare systems in many of the involved

Table 1. Major Features of the Treponematoses

	Venereal syphilis	Endemic syphilis	Yaws	Pinta
	T. pallidum subsp. *pallidum*	*T. pallidum* subsp. *endemicum*	*T. pallidum* subsp. *pertenue*	*T. carateum*
Age of infection	15–40	2–10	5–15	10–30
Occurrence	Worldwide	Africa, Middle East	Africa, South America, Oceania, Asia	Central and South America
Climate	All	Dry, arid	Warm, humid	Warm
Transmission				
Direct				
Venereal	Common	Rare	No	No
Nonvenereal	Rare	Common	Common	Probable
Congenital	Yes	Unproven	No	No
Indirect				
Contaminated utensils	Rare	Common	Rare	No
Insects	No	No	Possible	No
Reservoir of infection	Adults	Infectious and latent cases	Infectious and latent cases	Infectious cases
Ratio of infectious to latent cases	1:3	1:2	1:3–5	?
Late complications	+	+	+	+
Skin, bone, cartilage	+	+	+	No
Neurologic	+	Unproven	No	No
Cardiovascular	+	Unproven	No	No

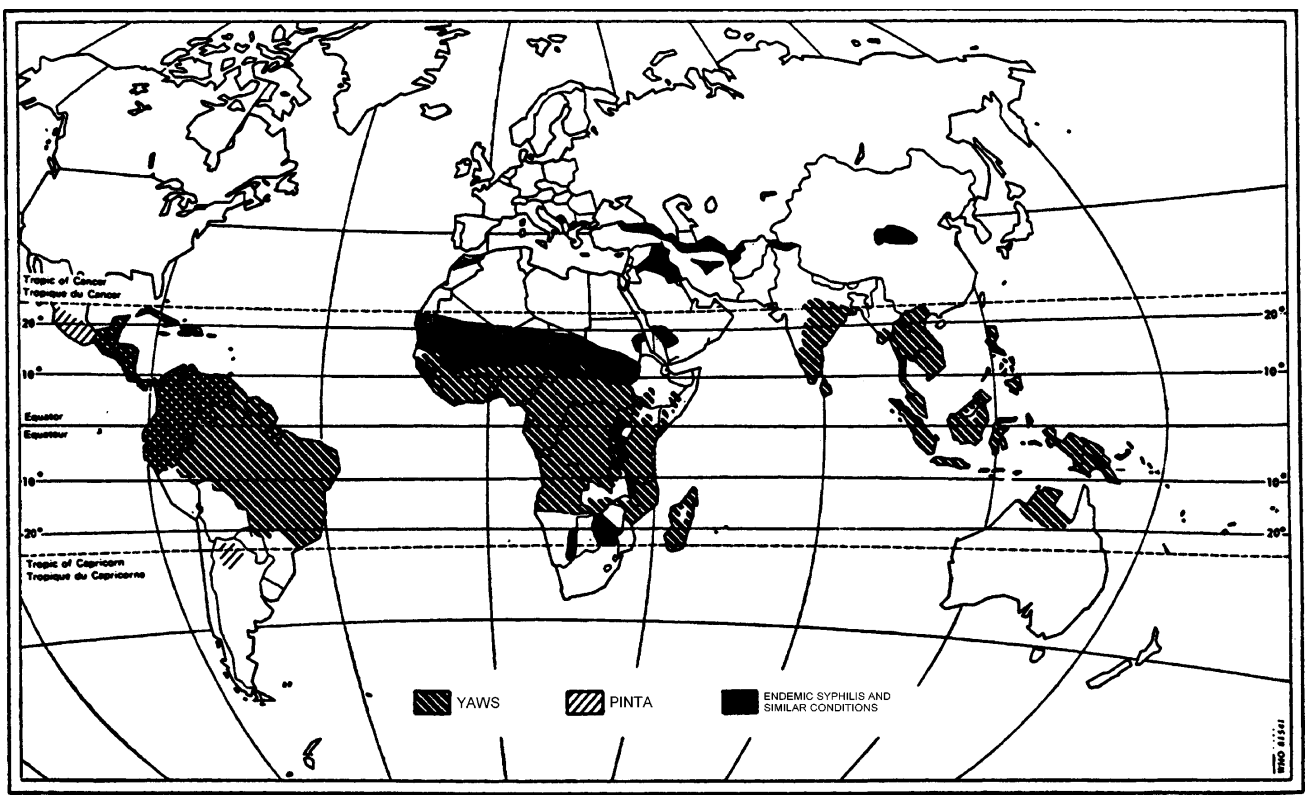

Figure 1. Geographic distribution of the endemic treponematoses in the early 1950s.

countries.[13] Importantly, these first campaigns focused solely on clinical (not latent) cases, and thus made only a dent in the total number of yaws cases.

The development of long-acting penicillin preparations, producing a treponemicidal blood level for 3–4 weeks after a single injection, made mass treatment of treponemal infections much more feasible.[14] In 1949, the nascent World Health Organization (WHO) agreed to conduct coordinated mass treatment campaigns against yaws, endemic syphilis, and pinta. Haiti and the Dominican Republic were chosen as the sites for pilot projects, and the initial campaigns confirmed the efficacy of single injections of penicillin aluminum monostearate in mass treatment, the need to examine at least 90% of the target population during the initial survey, and the need to conduct re-surveys of treated populations to treat new cases and re-infections.[14] With logistical support from the United Nations International Children's Emergency Fund (UNICEF), the WHO extended the program to 46 countries, and from 1952 to 1968, an estimated 160 million persons worldwide were examined during initial surveys, an additional 300 million examined during re-surveys, and 50 million persons with clinical or latent infections and their contacts were treated with penicillin. Overall endemic treponematosis disease prevalence was reduced by 95%,[14,15] and at the end of these campaigns the endemic treponematoses appeared to be on their way to extinction, especially in view of the improvements in living standards that occurred in many of the endemic areas.

By the beginning of the 1970s responsibility for controlling and eradicating remaining cases was transferred to individual national and local governments, and the vertical mass treatment approach was switched to one integrated into the basic health services system. This approach was far less effective, and by the end of the decade many formerly endemic areas saw a resurgence in endemic treponematoses cases, especially among children and young adults born after penicillin treatment campaigns were completed. By the early 1980s the number of persons infected with the endemic treponematoses was estimated at 2.5 million,[6] and under WHO recommendation several countries reinstituted mass treatment campaigns, with varying success.

3. Methodology

Until the late 1980s current epidemiological data on the endemic treponematoses were available from the regional offices of the WHO and its *Weekly Epidemiological Record*[16] and the proceedings of yaws symposia.[17–19] Over the last 15 years most national governments have ceased collecting epidemiological data on the endemic treponematoses, and neither yaws, endemic syphilis, nor pinta is a disease that member states must report to the WHO. The most recent estimates come from the 1998 WHO World Health Report and from expert analysis of several recent articles in the medical literature that focus on surveys in particular communities.

3.1. Sources of Mortality Data

There is little pathological or epidemiological evidence that the endemic treponematoses acquired in childhood subsequently cause fatal late cardiovascular or central nervous system (CNS) complications usually associated with venereal syphilis. Where venereal syphilis is prevalent together with yaws or endemic syphilis, however, it is impossible to differentiate visceral, ocular, and neurological lesions caused by venereal syphilis from those that might result from yaws or endemic syphilis.[20,21]

3.2. Sources of Morbidity Data

The WHO, through analysis of data reported to its regional offices, reported its latest estimates in its 1998 World Health Report. Several more recent articles in the medical literature provide data on trends in particular endemic areas.

3.3. Surveys

Clinical and seroprevalence surveys for yaws and endemic syphilis were conducted by many African and Asian countries in the 1980s as part of a WHO initiative to control the resurgence of these diseases. Since then, individual countries have sporadically carried out surveys in areas of high prevalence.

3.4. Laboratory Diagnosis

3.4.1. Isolation and Identification of the Organisms. The pathogenic treponemes cannot be cultured *in vitro,* but their identification by dark-field microscopy of lesion exudate provides instant diagnosis. This approach is, however, becoming less common as it takes trained and experienced staff to properly identify the pathogenic treponemes. A more sensitive and specific[6] method is direct fluorescent antibody (DFA) identification of treponemes on a slide of lesion exudate, done at a reference laboratory.

3.4.2. Serological and Diagnostic Methods. Serological tests routinely employed in seroprevalence surveys are the venereal disease research laboratory (VDRL) and

rapid plasma reagin (RPR) tests.[22] These tests are not specific, but their reactivity and titer in an appropriate clinical setting give a good idea of the prevalence of latent treponemal infection. Specific treponemal antibody tests (e.g., *Treponema pallidum* hemagglutination test and fluorescent treponemal antibody absorption test) can be used to confirm a diagnosis, but these antibodies stay positive for many years after infection, even if successfully treated. No serological or microscopic test to date can distinguish between *T. pallidum* subspecies or between *T. pallidum* and *T. carateum*.[23]

4. Biological Characteristics of the Organism

The members of the genus *Treponema* fall under the Spirochaetaceae family which also contains the *Borrelia* species. The four treponemes pathogenic in humans cause clinically distinct diseases, and for this reason they were initially classified as four distinct species. Subsequent DNA hybridization studies caused a reclassification into the current scheme, in which three of the treponemes are subspecies of *T. pallidum*: *T. pallidum* subsp. *pallidum*, *T. pallidum* subsp. *endemicum*, and *T. pallidum* subsp. *pertenue*.[1,2] The fourth treponeme, *T. carateum*, has been impossible to isolate for comparative genetic studies,[6] and so it continues to be classified as a separate species. *Treponema pallidum* and its subspecies are obligate anaerobes. Difficulties in culturing these organisms in a cell-free *in vitro* system have limited comparative studies of their genetic and antigenic structure, but recent experimenters have used immunoblot techniques, specific monoclonal antibodies, and synthetic peptides to look for antigenic differences, so far without success.[6] Prototype strains of yaws and endemic syphilis treponemes produce lesions in only a few experimental animals. The lesions produced in these animals are similar to those occurring during the early stages of infection in man. Subtle differences in virulence and lesion morphology exist between subspecies and strains of *T. pallidum endemicum* and *pertenue*. Similar subspecies and strain differences exist in most species of pathogenic bacteria.

The pathogenic treponemes are exquisitely sensitive to penicillin. Their multiplication by binary fission takes an estimated 32 h to complete[24] and is the reason why long-acting penicillin preparations that produce low but persistent penicillin blood concentrations for 3–4 weeks are recommended for therapy. Importantly, in the past decade there have been a few reports of penicillin treatment failures in Papua New Guinea[25] and Ecuador,[26] a trend that could become very problematic if resistance grows.

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

Since most national governments have stopped collecting epidemiological data on the endemic treponematoses, the current number of cases is unknown. The latest figures from the WHO in its 1998 World Health Report put the estimated worldwide prevalence at 2.5 million, with an annual incidence of 460,000 cases.[27] However, a high percentage of latent cases and the prevalence of "attenuated," less readily diagnosable, yaws and endemic syphilis in areas of reduced transmission[28] may mean that the actual numbers are even higher. The large majority of current endemic treponematoses cases are yaws, with yaws-endemic foci remaining in West and Central Africa, Southeast Asia, on some of the Pacific islands including Papua New Guinea, Central America, and northwest South America.[6] In certain African, Asian, and South American countries, prevalence levels are thought to approximate the pre-penicillin campaign levels.[23] Endemic syphilis continues to be seen in high numbers among nomadic and semi-nomadic tribes in the Middle East (especially Saudi Arabia) and in Sahel Africa.[29,23] Treatment campaigns and improving standards of living have dramatically decreased the prevalence of pinta, and it is now believed that the disease exists only in a number of isolated, rural, indigenous communities in Mexico and South America, especially in parts of the Brazilian Amazon rain forest.[30]

5.2. Epidemic Behavior and Contagiousness

Yaws is highly contagious and can spread rapidly in susceptible populations, such as rural communities with poor hygiene, minimal clothing, and limited access to medical services.[6] Endemic syphilis tends to affect isolated, nomadic populations, and its epidemic potential is less than that of yaws. Indeed, the prevalence of endemic syphilis has decreased because of small improvements in the living standards and personal hygiene of many populations during the last century and a half, even before the advent of modern treatment.[6] In contrast to the other endemic treponematoses, pinta is very difficult to transmit by person-to-person contact and has little epidemic potential.

5.3. Geographic Distribution

The worldwide distribution of the endemic treponematoses in the mid-1980s is shown in Figure 2. Humid, rural, tropical areas of the world, particularly throughout Africa,

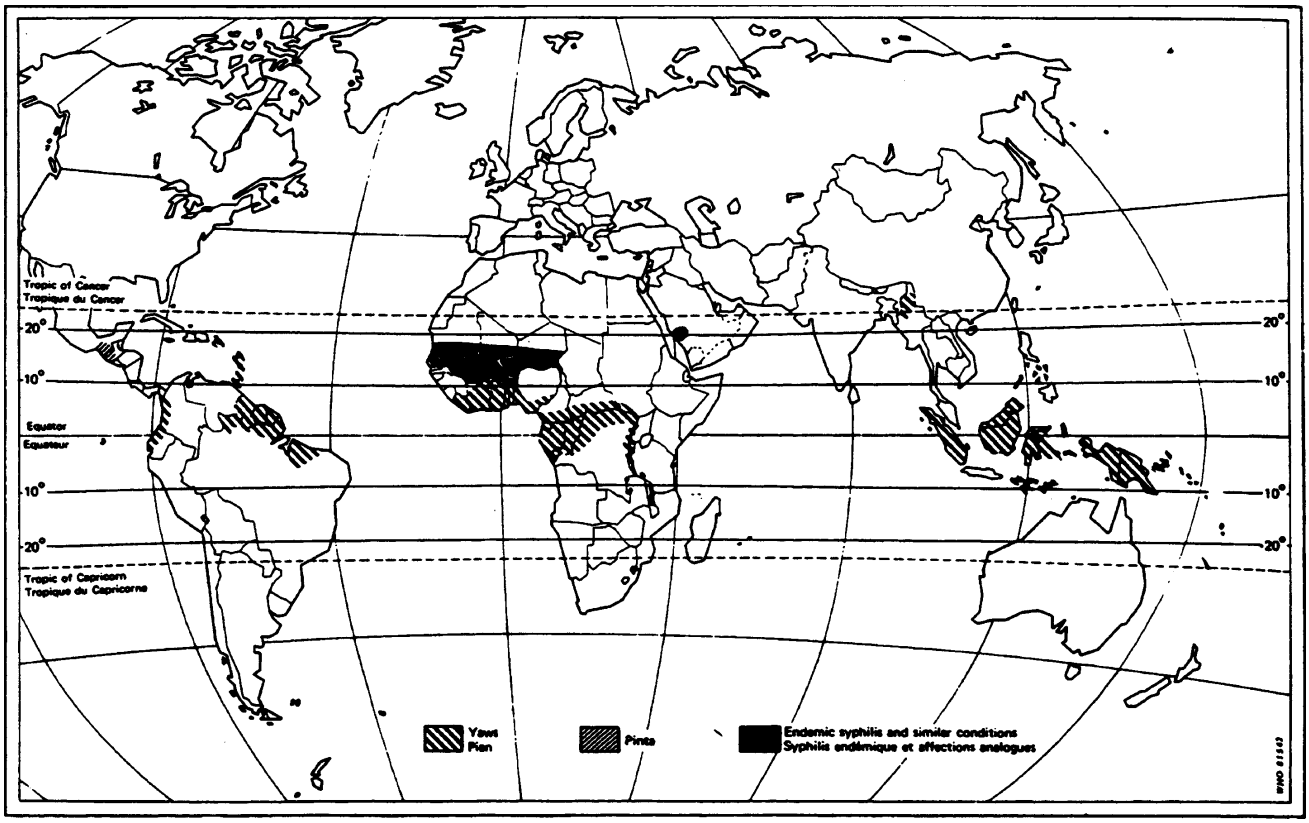

Figure 2. Geographic distribution of the endemic treponematoses in the 1980s.

are hosts to yaws, whereas endemic syphilis exists mainly in dry, arid regions of the eastern hemisphere, such as Saudi Arabia and the Sahel countries of Africa.[28] Pinta, once endemic to Central and South America, was thought to have been extinct (with the exception of remote areas of the Amazon rain forests) since 1975.[31] However, a remote case of pinta diagnosed in a woman who was visiting Austria (but who had lived in Cuba for 7 years) indicates that the disease may in fact still be prevalent in once-endemic areas.[32]

5.4. Temporal Distribution

There is no seasonality in occurrence of the endemic treponematoses, but the number, morphology, and infectiousness of cutaneous yaws lesions change during the wet and dry seasons in Africa and Asia. The high humidity associated with seasonal rains promotes an exuberant growth of papillomas and the survival of treponemes in their serous exudate, thus increasing infectiousness and the probability of person-to-person transmission. The skin is also softened by high humidity and is more susceptible to abrasions and lacerations, which are a portal of entry for treponemes. Lesions become less numerous during the dry seasons, and the papillomas tend to occur mainly in moist areas of the body, such as the axilla and groin.[6].

5.5. Age

In endemic areas, yaws is usually acquired before 15 years from infected siblings or playmates, and active early lesions are found almost exclusively in this age group. Endemic syphilis tends to occur in family groups, with the infection being acquired first by children, who then spread it to susceptible adults. Pinta usually first appears in susceptible adults.

5.6. Sex

Pinta tends to occur more frequently in men, but there is no sexual predilection for yaws or endemic syphilis.

5.7. Race

Race is not a factor.

5.8. Occupation

The diseases have no relationship to occupation per se, but the vast majority of those affected live in communities that survive by subsistence farming.

5.9. Occurrence in Different Settings

These treponematoses are usually found within families and among playmates.

5.10. Socioeconomic Factors

The endemic treponematoses are prevalent today in impoverished, remote, and rural populations lacking adequate clothing, water, sanitation, and medical care.

6. Mechanisms and Routes of Transmission

Transmission of yaws occurs by direct skin-to-skin contact, particularly by breaks in the skin barrier. Fingers contaminated with fresh lesion exudate readily transmit the viable treponemes from one individual to another. Various species of flies, particularly nonbiting flies (*Hippelates pallipes*), have also been implicated in the transmission of yaws.[6]. However, the efficiency of such transmission by flies is probably epidemiologically insignificant.

Endemic syphilis can be transmitted directly by person-to-person contact or indirectly by sharing of drinking cups contaminated with treponemes present in the serous exudates from lesions on the oral mucosa or at the corners of the mouth.

Transmission of yaws or endemic syphilis can occur during sexual intercourse, providing one partner has infectious lesions in the genital area, and the other is susceptible to infection. Unlike venereal syphilis, however, congenital transmission of yaws or endemic syphilis has not been convincingly documented. Indeed, experiments in the guinea-pig model[33] demonstrated a lack of transplacental transmission of *T. pallidum* subsp. *pertenue*.

The route of transmission of pinta is not clearly elucidated.[28] Most likely, transmission occurs through prolonged intimate contact with an adult with active disease. Therefore, household members of an infected individual are more likely to acquire the disease. However, infection rates are low, even between married couples.

7. Pathogenesis and Immunity

The endemic treponematoses manifest histopathological changes and serological responses that closely resemble those of venereal syphilis. The only practical means of comparing their pathogenicity is by experimental animal infections. *Treponema pallidum* spp. *pallidum* is more invasive and pathogenic than *T. pallidum* spp. *pertenue*. *Treponema carateum* is pathogenic only for man and higher primates.

Like venereal syphilis, infection with nonvenereal treponematoses produces localized lesions. In particular, a granuloma is the prototypical pathological lesion of both yaws and endemic syphilis. This reflects a strong, delayed hypersensitivity response to the presence of treponemes in skin and bone. Throughout the course of the disease, normal skin and bone are replaced by scar tissue, causing disfigurement and occasional disability. Unlike venereal syphilis, however, cardiovascular, neurological, and visceral lesions are extremely rare.[20]

Protective immunity waxes and wanes during the course of untreated yaws and endemic syphilis, especially during the 5 years following initial infection. In studies performed by Turner and Hollander,[8] this immunity was shown to be specific to the treponemal subspecies. Later experiments performed in the hamster model[34] showed that immunity against re-infection with the homologous organism was not absolute among different *T. pallidum* species. This is manifested by the reappearance of infectious cutaneous lesions, and is the reason why penicillin must be given to asymptomatic persons living in highly endemic communities who are very likely to have latent infections.

8. Patterns of Host Response

The manifestations of yaws and endemic syphilis are usually mild, with lesions restricted to the skin and mucous membranes. The clinical features occur in both early (which includes primary and secondary lesions) and late stages.[28] The lesions usually heal spontaneously after several months, but can result in more aggressive disease with destruction of skin and bone. Those who suffer severe disease may be genetically predisposed.

In areas where infection with the nonvenereal treponematoses are endemic, serological surveys invariably detect more individuals with latent infections than those with clinically manifested disease. Many of these patients have no recollection of early disease manifestations, suggesting that asymptomatic infection is frequent or that their earlier lesions were inconsequential or mistakenly interpreted as something else.

8.1. Clinical Features

The incubation periods of yaws, endemic syphilis, and pinta are directly related to the number of treponemes in the

inoculum. The initial lesion(s) appears at the portal of entry after an incubation period of 9–90 days.

Pinta, yaws, and endemic and venereal syphilis are chronic infections with early and late clinical manifestations. Early lesions are infectious and usually are not destructive, whereas late lesions are not infectious but are destructive.

8.1.1. Pinta. Initially, one or more painless, papular lesions form on the upper or lower extremities, face, or other exposed areas. Individual lesions expand to form irregular, reddish, or bluish patches 5–10 cm in diameter with raised borders. Several weeks or months later, disseminated lesions ("pintides") with a morphology similar to that of the initial lesion appear on different parts of the body. Hyperkeratosis with desquamation, itching, and formation of fissures within the borders of lesions is common and may be accompanied by lymph node enlargement. The skin is the only organ pathologically affected.

In the late stage, the involved skin becomes atrophic, and the bluish coloration of the initial lesion caused by accumulation of melanin pigment in the dermis fades. This leaves the patient disfigured by red, blue, and white spots on the face, neck, arms, hands, legs, and feet. Eventually the lesions cause sclerosis of the dermis and depigmentation, leaving scars that resemble vitiligo. The evolution from the time of the appearance of the initial lesion to its late depigmented scarring may be several years.

8.1.2. Yaws. The initial lesion of yaws is usually a papule. This painless, pruritic, elevated lesion appears at the site of treponemal invasion after an incubation period of 9–90 days. The site of entry is often a preexisting abrasion, laceration, or insect bite. The treponemes multiply at the infection site, invade subcutaneous lymphatics, cause local lymph node enlargement, and spread systematically through the bloodstream.

The yaws papule enlarges to become a papilloma (frambesioma) that lasts 3–6 months. It may ulcerate and become secondarily infected with bacteria or heal spontaneously, thereby creating a brief period of latency. Secondary yaws lesions then appear in crops on the skin near the initial lesion or elsewhere on the body, including bone and cartilage, as a result of systemic spread and auto-inoculation. Constitutional symptoms are rare, but nocturnal pain of the long bones of the leg due to periostitis and papillomas on the soles of the feet preventing weight bearing are common.

Secondary papillomas are prominent during wet seasons and involute to form micropapules and macules during dry seasons. The lesions heal spontaneously and do not leave permanent scars unless they ulcerate and become secondarily infected by pyogenic bacteria. The disease then enters a noninfectious latent period that may last the lifetime of the patient.

During the first 5 years after infection, the state of latency may be interrupted at any time by the reappearance of infectious yaws lesions. Destructive gummatous lesions appear in the skin or osseous tissue in about 10% of those infected, usually several years after the initial infection. These late lesions mutilate and cripple.

8.1.3. Endemic Syphilis. A primary lesion is rarely seen in endemic syphilis. The first lesions to appear are painless ulcerations on the oropharyngeal mucosa. These are followed by a variety of skin, bone, and joint lesions that are indistinguishable from those of yaws. Skin lesions prefer the moist body surfaces such as the axillary and genital areas. Angular stomatitis or split papules at the corners of the mouth are more common than in yaws and are ideally situated to contaminate drinking vessels.

Osteoperiostitis of the long bones occurs more frequently in endemic syphilis than in yaws. It usually involves the long bones of the lower extremities, causing nocturnal leg pains. Gummas of the nasopharynx, skin, and bone are common in late endemic syphilis and may progress to destructive ulcers. Such ulceration may destroy nasal tissue, producing a terrible disfiguring lesion known as gangosa. Chronic osteoperiostitis and gangosa are still frequently encountered among adult nomadic Bedouins of the Arabian peninsula[29] and occasionally in children and adults suffering from late yaws in West Africa.[22]

8.2. Diagnosis

A presumptive diagnoses of yaws, pinta, or endemic syphilis can usually be made by careful assessment of the clinical features that characterized each infection in appropriate epidemiological settings. Pinta is easily differentiated clinically from yaws, and endemic and venereal syphilis. The differentiation between sporadic cases of yaws and endemic syphilis may not be possible because they may coexist in the same geographic area and their clinical and serological manifestations are indistinguishable.

The most sensitive and specific diagnostic test for treponemes is direct fluorescent antibody (DFA) testing, while the most common confirmatory testing is fluorescent treponemal antibody absorption test (FTA-ABS).[6] Direct fluorescent antibody testing usually requires a central laboratory. Dark-field microscopy, once popular, has decreased as a diagnostic measure due to limited access in endemic areas. With this technique, motile treponemes appear as brilliant coiled threads on a dark background. Lesion exudate can also be collected and fixed on microscope slides and sent to a reference laboratory for microscopic examination using *T. pallidum*-specific monoclonal antibodies.[22] It does not, however, provide differentiating morphologic criteria.[28]

A number of different serological tests are used to detect antibodies produced in response to treponemal infections. These tests were originally designed for use in venereal syphilis and none are specific for a given treponematosis. The most commonly used serological tests are the VDRL and RPR tests, which are highly sensitive in the early stages of disease. They are widely used in screening programs to detect latent yaws or endemic syphilis.

Following adequate penicillin treatment, the titer of VDRL and RPR serological tests declines but, depending upon the duration of the infection, may remain positive for several years or a lifetime. Such is often the case in persons who immigrate from yaws- or endemic syphilis-endemic areas to parts of the world where only venereal syphilis is encountered. Based on reactive serological tests for syphilis, many of these patients are diagnosed and treated inappropriately for active latent venereal syphilis.

9. Control and Prevention

The provision of adequate clothing and soap and water would greatly reduce the transmission of pinta, yaws, and endemic syphilis. Marginal improvements in standards of living together with occasional access to medical care may partly explain why the mutilating complications of yaws and endemic syphilis are seen much less frequently today compared to the preantibiotic era.

The experience gained from pilot programs of the 1950s established a set of principles and procedures that is still valid today and should be used to control yaws and endemic syphilis.[22] The most important principle is to conduct periodic assessments of communities or nomadic groups where one or more members have infectious lesions resulting from recently acquired or relapsed infections. The population of a village or family group should be seen and evaluated at an initial treatment survey and those with active disease should be treated with a single intramuscular injection of 2.4 million units of benzathine penicillin (half-doses for children under 12 years) as should all of their household members and playmates. Control activities should be expanded in such a way that an ever-enlarging disease-free area is established, so that reintroduction of yaws or endemic syphilis by persons from untreated areas is minimized. Because penicillin is inexpensive compared to other medications, many authorities recommend that treatment be given to entire communities that have one or more infectious cases.[14] Treated populations should be reexamined for active yaws within 6 months and at intervals thereafter so that missed cases and their contacts can be treated. The price of freedom from yaws and endemic syphilis is eternal vigilance.

9.1. Antibiotic and Chemotherapeutic Approaches to Prophylaxis

Prophylaxis other than penicillin treatment of contacts of infectious cases of yaws and endemic syphilis is not indicated.

9.2. Immunization

Although theoretically possible to develop, a treponemal vaccine does not exist and the prospects for one are remote.

10. Unresolved Problems

The lack of a cell-free *in vitro* culture system has limited studies of the genetic structure and the immunopathogenesis of the pathogenic treponemes. Control of the endemic treponematoses may result in increased transmission of venereal syphilis, due to loss of partial cross-immunity, with congenital transmission and the serious and potentially fatal cardiovascular and neurological complications. The perennial problem posed by the endemic treponematoses is the low priority given to them by most health authorities when faced with limited resources and more serious disease problems.

CHAPTER 38

Tetanus

Steven G.F. Wassilak and Katrina Kretsinger

1. Introduction

Tetanus is a noncommunicable infectious disease of humans and certain animal species, acquired usually through environmental exposure. *Clostridium tetani* is an anaerobic, spore-forming bacilli ubiquitous in the soil. The spores germinate to vegetative bacilli when introduced into the soft tissues of the host under conditions in which the partial pressure of molecular oxygen is low. The vegetative organisms produce a potent neurotoxin that acts on the central nervous system (CNS), leading to the muscular contractions characteristic of the illness. Tetanus can be prevented by active immunization with tetanus toxoid, which is chemically inactivated toxin, or by passive immunization with specific immune globulin as part of postexposure wound prophylaxis. Tetanus toxoid, which protects by inducing production of neutralizing antibodies, is both highly immunogenic and safe. Nearly 100% of recipients of a primary immunization series are protected. Due to increasing use of tetanus toxoid-containing vaccines over decades throughout the world, tetanus is becoming a rare disease; it is relatively more frequent in unimmunized older age groups and in areas where immunization programs are less effective. Although a significant proportion of the global tetanus case burden remains in under-immunized adults and children, a major burden of tetanus in the world is borne by neonates born to mothers who are not adequately immunized and are infected at or soon after birth. However, major progress has been made in the initiative to eliminate neonatal tetanus as a significant public health problem.

2. Historical Background

The clinical characteristics of tetanus are detailed in an ancient Egyptian papyrus and described in the writings of Hippocrates. However, the etiology of tetanus remained unknown until 1884, when two studies were published indicating an infectious process. Carle and Rattone[1] injection drug the contents of a pustule from a fatal human case into the sciatic nerve of rabbits that led to the signs of typical tetanus; the disease could subsequently be passed to other rabbits from infected nervous tissue. Nicolaier[2] induced tetanus in experimental animals after injection of soil samples; he observed gram-positive bacilli in the exudate at the inoculation site but not in nervous tissue, leading him to hypothesize that a locally produced poison led to the neurological symptoms. In 1886, Rosenbach[3] observed spore-forming bacilli in the exudate obtained from a case in a human. In 1889, Kitasato[4] demonstrated that *C. tetani* spores survived heating and germinated under anaerobic conditions; injection of pure cultures reproducibly caused disease in animals. After Behring and Kitasato[5] identified and purified the toxin in 1890, they showed that repeated inoculation of animals with small quantities of toxin led to the production of antibodies in survivors. Preparations of antitoxin from animal sera, particularly horses, became the first means of preventing and treating tetanus. In 1924, Descombey[6] prepared toxoid (chemically altered toxin), which induced neutralizing antibodies without causing illness. Active immunity induced by this preparation opened the way for large-scale tetanus prophylaxis.

3. Methodology

3.1. Sources of Mortality Data

In the United States and most developed countries, data on tetanus deaths come from national compilations of death certificates (i.e., vital statistics system) listing tetanus as the underlying or contributing cause of death.[7] In such countries, death data probably may be a reasonable, albeit incomplete, estimate of the total deaths from diagnosed tetanus. The National Center for Health Statistics (NCHS) compiles death certificate information from all deaths occurring in the United States.

However, in developing countries where the great majority of deaths occur in the neonatal period primarily outside the hospital, death certificate information may not be available or reliable. In those settings, the completeness of reporting of tetanus deaths, and particularly neonatal tetanus, may be <5%,[8] and only with community-based surveys could accurate estimates of mortality for neonatal tetanus be obtained.[9,10]

3.2. Sources of Morbidity Data

In many developed countries, tetanus is a reportable disease. In the United States, tetanus became notifiable in 1947. The Council of State and Territorial Epidemiologists established in 1990 a uniform set of criteria for disease reporting. The recommended case definition revised in 1996 for a clinically compatible case of tetanus is "Acute onset of hypertonia and/or painful muscular contractions (usually of the muscles of the jaw and neck) and generalized muscle spasms without other apparent medical cause". A confirmed case is a clinically compatible case as reported by a healthcare professional. Case notification is passive, depending on physician initiative, which makes reporting efficiency highly variable. It is likely that only a proportion of the cases actually occurring are reported to national health authorities. In the United States, additional available information on cases reported to the Centers for Disease Control and Prevention (CDC) includes a patient's immunization status, wound history, medical history, postexposure prophylaxis, treatment, and outcome. In the United States during 1972–2005, 614 tetanus deaths were reported to the NCHS compared to 528 deaths reported via the passive surveillance system maintained by the CDC. Also during this period, reported death-to-case ratios (using CDC reports only) have declined from approximately 50 to 10% overall, but ratios vary depending on age and immunization status. Case series from other developed countries have reported death-to-case ratios as low as 10–20%.[11–14] It is likely that there is a bias toward reporting the most severe cases in passive surveillance systems. By matching demographic information for individuals with death following tetanus from both NCHS mortality data and tetanus morbidity reporting, the efficiency of the reporting of tetanus deaths in the United States in the 1980s has been estimated at 40% to CDC and 60% to NCHS.[15] It is likely that substantial under-reporting of cases (and deaths) continues. Similar under-reporting has been estimated for other developed countries.[8]

3.3. Serological Surveys

Serological tests measure the level of circulating antitoxin, which generally correlates with protection from disease when above a threshold of 0.01 International Units (IU)/ml.[16–18] Detectable antitoxin is induced almost exclusively through immunization. Tetanus disease generally does not result in production of circulating antitoxin.[19–21] Therefore, serological surveys, particularly in developed countries, serve an important purpose to measure the impact of immunization in inducing and maintaining population immunity and can supplement the data on the epidemiological characteristics of reported disease.

A national, population-based serosurvey of more than 18,000 people older than 5 years in the United States was conducted during 1988–1994 indicating substantial age and sex differences in antibody prevalence.[22]

Toxin neutralization assays in mice provide results that correlate well with clinical protection since they assess prevention of disease by biologically active antitoxin in a living host, although there is no universally accepted test protocol.[16] Injecton drug the animals with various dilutions of serum and a lethal dose of tetanus toxin allows detection of levels as low as 0.001 IU/ml when compared to a reference serum.[23] However, because the test is time consuming, expensive, and requires animal hosts, a variety of in vitro tests have been employed. These include passive hemagglutination assays (PHA), enzyme-linked immunosorbent assays (ELISA), latex agglutination, and a variety of other methods.[24–27] Sensitivity and specificity vary with the technique. PHA and, more predominantly, ELISA are currently the in vitro techniques used most often to determine tetanus antitoxin levels in population studies. Both assays, are relatively sensitive and specific, although specificity decreases at low antitoxin levels.[24,27] Since PHA measures both IgG and IgM[27] whereas neutralization results from IgG antitoxin,[28] measurement of antitoxin by PHA shortly after the first or second dose of toxoid may report falsely high antibody levels secondary to detection of IgM.

ELISA assays correspond closely with the in vivo neutralization assays at moderate to high levels of antitoxin, but the correlation for standard ELISA is suboptimal at low levels of antitoxin (under 0.2–0.1 IU/ml). Decreased specificity of ELISA at low antitoxin levels can be due to nonspecific antibody binding to contaminant proteins and/or detection of antibody with low avidity to non-neutralizing epitopes. In the United States, for the licensure and regulation of tetanus toxoid-containing products, the US Food and Drug Administration uses 0.1 U/ml when determined by standard ELISA as the surrogate measure of the minimal level of protection. To increase ELISA specificity at low antitoxin levels, modifications such as competitive-antigen or toxin-binding inhibition have been introduced. The comparative value of serological tests for tetanus has been reviewed.[27]

3.4. Laboratory Diagnosis

Tetanus is primarily a clinical diagnosis and the laboratory usually plays little role. Some cases present without a history or evidence of a recent wound. Of cases with wounds, anaerobic culture of wounds is frequently negative, although the yield can be improved by inoculating part of the specimen in cooked-meat medium and heating to 80°C for 5–20 min to destroy nonsporulating competing microorganisms.[29] The organism has been grown from wounds in the absence of clinical symptoms or signs. Serological tests also are of little use, since most tetanus patients do not mount a serological response against the toxin.[30] Although low levels of circulating antitoxin at the time of onset of illness could suggest susceptibility to the agent, detection of antitoxin does not eliminate the diagnosis; several reports have documented antitoxin levels much higher than 0.01 IU/ml (most by in vitro methods, some by neutralization assay) in some patients with classic tetanus at the time of presentation.[27,31] Although such instances are probably rare, tetanus must still be considered in the differential diagnosis as long as the illness is clinically compatible even when circulating antitoxin is greater than 0.01 IU/ml. Detection and quantification of tetanus toxin in serum appear to be diagnostic, although such determination remains a research tool at present.

4. Biological Characteristics of the Organism

C. tetani is a gram-positive, spore-forming, anaerobic bacillus.[29] Flagella attached bilaterally on nonsporulating bacteria add motility. The organism typically measures 0.3–0.5 μm in diameter and 2–2.5 μm in length, although long filamentous forms may be seen in culture. Spores typically form in the terminal position and give the organism its characteristic drumstick-like appearance.

While there may be some tolerance for oxygen when the oxidation–reduction potential is low, for the most part *C. tetani* can be considered an obligate anaerobe. It grows optimally at 33–37°C, although depending on the strain, growth can occur from 14 to 43°C. The organism can be grown on a variety of anaerobic media such as cooked meat, casein hydrolysate, and thioglycolate. Growth is usually characterized by production of gas with a fetid odor. Compact colonies formed in a meshwork of fine filaments are usually seen on blood agar. Addition of reducing substances at neutral to alkaline pH enhances growth.

Formation of spores can be promoted or inhibited by a variety of factors including media composition, temperature, and pH.[22] Sporulation is enhanced in aging cultures and by physiological temperatures (i.e., 37°C), and in the presence of oleic acid, phosphates, 1–2% NaCl, and manganese. In contrast, low pH, extremes of temperature (< 25 or > 41°C), glucose, assorted saturated fatty acids, antibiotics, and potassium can inhibit sporulation.

Spores are highly resistant to environmental agents and may persist in soil for months to years, if not exposed to sunlight.[29] Spores can be destroyed by a variety of disinfectants and heat, although susceptibility varies by agent. Aqueous iodine or 2% glutaraldehyde at pH 7.5–8.5 kills spores within 3 h. In contrast, phenol (5%), formalin (3%), chloramine (1%), and hydrogen hyperoxidates (6%) require 15–24 h to destroy spores. Spores are resistant to boiling, but heating to 120°C for 15–20 min will inactivate them.

C. tetani produces two exotoxins: tetanolysin and tetanospasmin.[29] Tetanolysin is an oxygen-sensitive hemolysin related to streptolysin and the theta toxin of *C. perfrigens* that may play a limited role in establishing infection.[29] Tetanospasmin, the cause of the clinical signs and symptoms of tetanus, is a highly potent neurotoxin that accumulates intracellularly during the logarithmic growth phase and is released into the medium upon autolysis. Toxin production is under the control of a plasmid.[32] The molecule of approximately 150,000 Da is synthesized as a single polypeptide chain that is cleaved into light and heavy chains bound by a disulfide bond when released into the medium.[33]

The toxin is one of the most potent poisons on a weight basis, although sensitivity varies considerably by species. Guinea pigs are particularly sensitive, with doses of 0.3 ng/kg usually fatal. About 1 ng/kg will kill a mouse, while the estimated minimum human lethal dose is < 2.5 ng/kg. Monkeys, sheep, goats, and horses also are extremely susceptible to the effects of the toxin, while cats, dogs, and particularly birds and poikilotherms are relatively

resistant.[34] The differences in species susceptibility cannot be explained by differences in circulating antitoxin but may be due to differences in toxin binding to peripheral motor neuron terminals.[29,35]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

In spite of the availability of a highly effective immunizing agent for decades, tetanus continues to exert a substantial health impact throughout the world. It is clear however, that while the number of cases of tetanus in neonates (tetanus during the first month of life), children and adults are decreasing, the past burden of neonatal tetanus had been greatly underestimated. Given its substantial impact in developing countries, the control of neonatal and nonneonatal tetanus is the subject of a major effort of Expanded Programme on Immunization (EPI) by routine immunization in infancy with diphtheria–tetanus–pertussis (DTP) and by immunization of women of reproductive age with tetanus toxoid.

In the 1960s, the incidence of tetanus neonatorum in developing nations had been estimated to be under 50,000 cases annually, or approximately 0.5/1,000 live births overall.[31] By 1973, recognizing problems in surveillance, the estimate of annual tetanus deaths worldwide shifted upward to 1 million, with 60–90% of that mortality ascribed to tetanus neonatorum.[36] However, in the 1980s, using more accurate information collected in community-based surveys of infant deaths, despite further advances in immunization of pregnant women, an estimated 1.2 million deaths due to neonatal tetanus (about 10 deaths/1,000 live births) and an estimated 30,000 deaths due to maternal tetanus were occurring each year.[9,37] At the same time, there were over 600,000 estimated cases of nonneonatal tetanus associated with an estimated 120,000–300,000 deaths.[38] Ongoing efforts in the prevention and elimination of neonatal tetanus have led to a decline in the estimated number of neonatal tetanus deaths per year; by 1988, there were 787,000 annual deaths (6 deaths/1,000 live births).[39] In 1989, the World Health Assembly of the World Health Organization (WHO) adopted a resolution to eliminate neonatal tetanus worldwide by the year 1995, and this was reaffirmed in 1990 at the World Summit for Children. The objective of eliminating neonatal tetanus—defined as less than one case per 1,000 live births for each health district—was not met by the target year, when an estimated 300,000 deaths due to neonatal tetanus occurred. Advances toward the goal were due in large part to the use of the "high-risk" approach toward prevention of neonatal tetanus, in which supplemental immunization campaigns for all women of childbearing age are held in selected high-risk areas identified by surveillance or other indicators. The impact of increasing immunization coverage of pregnant women with tetanus toxoid (from 9% in 1980 to 69% in 2006),[40] the success of targeted mass immunization in high-risk populations and the increasing prevalence of clean deliveries are currently estimated to prevent 1.3 million deaths each year due to neonatal tetanus. Despite this marked progress in prevention, approximately 180,000 neonatal tetanus deaths continue to occur each year as of 2002 (1.4 deaths/1,000 live births).[41] Continued improvements in vaccination coverage, hygiene and childbirth practices, and surveillance to identify remaining high-risk areas and target them for intensified intervention efforts, as well as continuing the strengthening of routine childhood immunization services, will contribute in further decreasing the global burden of maternal and neonatal tetanus.

In most developed countries, improved hygiene and childbirth practices (associated with an increasing proportion of births delivered by trained health professionals in hospitals), improvements in wound care, reduction in exposure to tetanus spores, and active immunization have led to major declines in tetanus incidence since the 1950s. In the United States, death certificate data from 1920 onward indicate a decline in annual tetanus death rates, which may have accelerated with the use of equine antitoxin in prophylaxis and treatment beginning in the mid-1920s (Figure 1).[42] Cases of tetanus have been monitored nationally since 1947, when the incidence was 0.39/100,000 total population; secular trends in tetanus occurrence since that time reflect changes in wound management and the use of toxoid. A continual decline in reported cases occurred until 1976 to about 0.04/100,000. Since then, a less pronounced decline in incidence rates has continued to the current 0.010/100,000.[43–50]

As indicated by the trends in overall death rates, the occurrence of neonatal tetanus in the United States was already on the decline prior to widespread tetanus toxoid use in women because of an increasing number of births in hospitals and improvements in postpartum hygiene. Deaths due to tetanus in those less than 1 year old, generally reflecting neonatal disease, declined from 0.64/1,000 live births in 1900 to 0.07 in 1930 to 0.01 by the 1960s. Using age-specific case reporting beginning in 1961, tetanus incidence could be directly monitored in those less than 1 year old and showed the same downward trend. From 1967 to 1968, the incidence rates of reported cases and of reported tetanus deaths in those less than 1 year old declined abruptly. This abrupt decline occurred primarily because of a decrease of reported cases in Texas following a dedicated effort to reach women at risk.[51]

Of the 32 cases reported in the first 4 weeks of life in the United States during 1972–2005, 29 were in infants

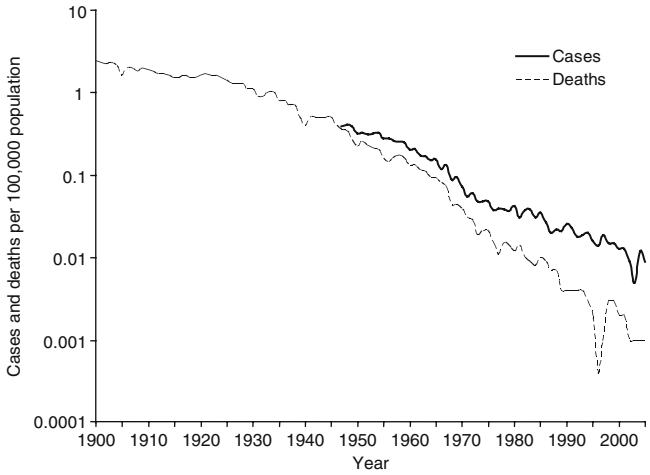

Figure 1. Reported mortality and case incidence rates of tetanus in the United States, 1900 to 2005. Not all states reported tetanus-associated deaths until after 1932; the estimated rates shown here are based on the population of the reporting states. National reporting of cases began in 1947. (Source: Centers for Disease Control and Prevention.)

born outside of a hospital.[49–50] Nineteen of the cases (59%) occurred in Texas, which had only 9% of US births. Only five mothers had a history of ever having received tetanus toxoid, and only one was known to have received more than one dose. Twenty of the 29 case-infants with known outcome survived. Only three cases of neonatal tetanus have been reported in the United States after 1989; one was to an Hispanic mother.

5.2. Epidemic Behavior

C. tetani spreads from the environment to humans generally through contamination of wounds. The organism cannot spread from person to person; tetanus is a non-contagious infectious disease. Nevertheless, outbreaks of tetanus in drug users (particularly among heroin addicts) have been reported.[52,53] In the United States during the 1990s, an increase of tetanus cases was reported among illegal injecton drug users, a recognized risk group, which halted a decline in the average annual incidence rates among persons 20–39 years of age.[46–48]

5.3. Geographic Distribution

C. tetani organisms are distributed across the globe. However, the greatest concentrations are in warm climates with moist, fertile soil.[54] The highest rates of tetanus disease have historically occurred in the developing world, particularly in countries near the equator.[36,54] Since the introduction and wide use of tetanus toxoid, geographic distributions reflect areas with under-immunized populations. In the United States, tetanus had been predominantly a disease of the Southeast; however, all regions currently report cases with approximately the same incidence. The occurrence of tetanus in regions at high altitude may be lower than in low-lying areas, although the reasons for this phenomenon are not understood.[55]

5.4. Temporal Distribution

In the pre-toxoid era, tetanus was generally distinctly seasonal, with a mid-summer or "rainy" season peak in temperate areas. This is consistent with multiplication of the organisms in the soil and sporulation but more likely also reflects more frequent host behaviors associated with injury during the warmer months.[44,54]

5.5. Age

As noted earlier, tetanus in developing countries occurs most frequently in neonates. Even in the United States in the 1950s, over one-third of tetanus deaths were in children under 1 year of age.[43] Aside from neonatal tetanus, the substantial proportion of victims in developing nations are older children and young adults. Wherever immunization programs are in place, tetanus occurrence declines.[54] In the face of immunization programs, age (and sex) distributions shift to reflect the under-immunized. In the United States since 1965, average annual age-specific tetanus incidence rates reflect declines in all age groups. However, less dramatic declines were registered in the elderly, while drastic declines were reported for younger age groups. Thus, in

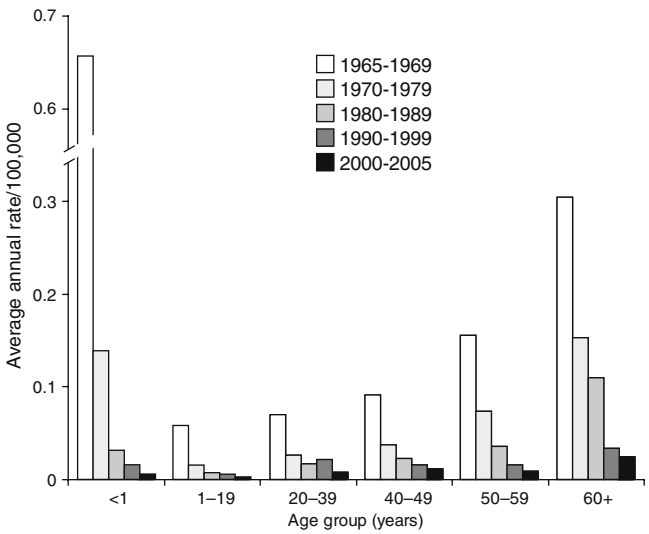

Figure 2. Age group-specific incidence rates of reported tetanus in the United States, 1965 to 2005. (Source: Centers for Disease Control and Prevention.)

recent years, the elderly have become the group at highest risk for tetanus (Figure 2). Among 142 cases reported in the United States in 2001–2005, the average annual incidence was 0.003 per 100,000 among persons less than 20 years of age compared with 0.024 per 100,000 among persons 60 years of age and older, an eightfold greater risk of acquiring tetanus.[50] A population-based serosurvey of immunity to tetanus conducted in the United States during 1988–1994 revealed that 70% of the population aged 6 years and above had tetanus antibody levels defined as protective. Nevertheless, the prevalence of tetanus antibody levels defined as protective declined with age, from >90% in children aged 6–11 years to 31% in people aged 70 years and older.[22]

5.6. Sex

In much of the world, reported tetanus appears to be more common in males than in females at all ages.[8,54] Although there may be a biologic reason, the general male predominance of neonatal tetanus in developing countries may in part be due to the possibility that parents of males may seek medical attention more frequently than do parents of females, or may apply substances to the umbilical stump associated with a higher risk of tetanus.[36] Among children and adults, males generally appear to have a somewhat higher reported incidence, which could perhaps be due to exposure factors, such as injury-incurring behaviors outdoors, and/or surveillance artifact.

In the United States for the period 1972–2005, two-thirds of the 32 neonatal tetanus cases were in males.[49,50] Outside of the neonatal period, the overall pattern of disease by sex seen in the United States is different from that seen in developing countries because males entering military service during World War II (and subsequently) were routinely vaccinated. During 2001–2005, among persons aged 1 month to 69 years, the incidence of reported tetanus was higher in males than females (0.011 vs. 0.005 per 100,000, respectively). Among persons aged 70 years and older (i.e., in a cohort born prior to routine infant and childhood immunization but in which the majority of males served in the military), the incidence was lower in males than females (0.015 vs. 0.030 per 100,000, respectively).[49,50]

5.7. Race

In the 1950s in the United States, nonwhite individuals had an incidence more than five times that in whites, and rates of neonatal tetanus were ten times higher.[43] In the United States in 1972–1989, the estimated average annual incidence rate was 0.02/100,000 for whites, 0.05/100,000 for blacks, and 0.12/100,000 for all other races.[49] These differences are felt to be attributable primarily to lower levels of tetanus toxoid immunization in the nonwhite populations, but also could reflect differences in health care following injury. For tetanus cases reported in the United States from 2001 to 2005, the incidence no longer differed between white and black populations.[50] However, adult, non-US-born immigrants, particularly Hispanics, may be at substantial increased risk for tetanus compared with the rest of the population, which may be attributable to a combination of injection drug use and underimmunization. From 1992 to 2001, Hispanics had an average annual incidence of tetanus that was 2.2 times higher than that of non-Hispanics; 38% of cases in Hispanics were among injection drug users. During these years, Hispanics made up 15% of tetanus cases that were not in injection drug users but 66% of cases among injection drug users.[49]

5.8. Occupation and Location

Among cases reported in the United States during 1972–2001, the relatively larger proportion of tetanus-associated wounds occurred in outdoor settings—in yard, farm, and gardening settings or following major trauma outdoors. During 1972–2001, however, case reports indicated that specific settings where tetanus-associated wounds were incurred in decreasing frequency indoors, in farm, gardening, hospital, and then factory settings.[45,49]

5.9. Occurrence in Different Settings

Because of wound and field conditions, war injuries frequently were associated with tetanus; it has been estimated that, prior to the availability of toxoid, 1 out of 100 serious wounds in battle conditions was complicated by tetanus. As a result of routine tetanus toxoid prophylaxis and vigorous prophylaxis in wound management, only 12 cases of tetanus occurred among 2.73 million wounded US Army personnel on all fronts in World War II (0.44/100,000) versus 70 out of 520,000 wounded in World War I (13.4/100,000).[56]

Parenteral drug abuse, both intravenous and subcutaneous, is known to place individuals at higher risk compared to the general population. Drug users may be at higher risk for tetanus because of nonhygienic injection practices; however, heroin is frequently mixed with quinine, which lowers the redox potential at the injection site, favors growth of anaerobes, and may create an ideal environment for *C. tetani* to germinate.[57] Patients with a reported history of illicit injection drug use accounted for 5% of tetanus cases overall from 1972 to 2001; drug use-associated cases increased during the 1990s to reach 12% of reported cases during 1992–2001.[49] Black tar heroin was reported as the common

injected drug for 71% of 14 heroin users among cases in during 1998–2000.[48]

Operative procedures, particularly bowel surgery, infrequently can put some individuals at risk, as can dental procedures, puerperal sepsis, and septic abortion.[37,58] Body piercings have been reported as a procedure associated with tetanus.[59,60]

5.10. Socioeconomic Factors

The incidence and complications of tetanus are inversely related to access to (1) routine prophylactic immunization, (2) immunization with appropriate wound care following wounds, and (3) care following onset of symptoms. Availability and use of these services probably correlate directly with socioeconomic status. Data collection on reported cases has not included indicators of socioeconomic status. Case-fatality ratios during 1972–1989 differed by race—31% for whites, 43% for blacks, and 34% for all other races—which may reflect differences both in access to health care and in immune status; in this case series, having two or more prior doses of tetanus toxoid put one at lower risk of death from tetanus.[49]

The differences in racial incidence in earlier series and the characteristics of mothers of patients with neonatal tetanus are strongly felt to reflect poorer immunization levels associated with lower socioeconomic status. The population-based serological survey of tetanus immunity in the United States also suggested that seroprevalence was positively correlated with education: the higher the educational level, the higher the tetanus seroprevalence rates.[22] These data suggest that compliance with routine vaccination recommendations (and access to postexposure wound prophylaxis) may also be correlated with higher educational levels.

6. Mechanisms and Routes of Transmission

6.1. Children and Adults

Outside the neonatal period, a variety of conditions have been associated with tetanus. Tetanus is caused by the in vivo elaboration of tetanospasmin. Spores of *C. tetani* are introduced through breaks in the skin epithelium; germination of the spores with production of toxin leads to disease. In the United States, information is available for 1,805 nonneonatal cases reported from 1972 through 2001.[49] Acute injuries were the predisposing event in 1,372 (76%), while chronic wounds or other medical conditions were associated with 289 cases (16%). Parenteral drug abuse was the only predisposing condition in 5% and was present in an additional 1%. For 8% of patients, no acute injury, chronic wound, or associated medical condition was known. Of the patients reporting acute injuries, puncture wounds were most common (38%) followed by lacerations (31%). The circumstances of the wound were known for 78% of these cases. Injuries in outdoor settings (e.g., yard, garden, or farm settings) accounted for 29% of cases with acute wounds, injuries incurred indoors accounted for 21% of cases, and 10% were incurred under special circumstances. These included animal bites and/or scratches in 3%, major trauma (burns, bullet wounds, and compound fractures) in 4%, and surgical wounds, many of which were contaminated (e.g., bowel wounds), in 3%.

Chronic medical conditions associated with tetanus included decubitus ulcers, gangrene, and frostbite, as well as dental and other abscesses and parenteral drug abuse.[45–49,52–54] Cases without known wounds or portals of entry have been described for many years.[54] In some instances, these are thought to arise from minor wounds not recalled by those patients.[61] Estimated incidence among persons with diabetes mellitus is higher than the general population by approximately five-fold.[49]

Other conditions associated with tetanus include foreign bodies and contaminated injections, e.g., illicit injected drug use, body piercing, and the practice of tattooing.[52,53,59,60]

6.2. Neonates

Neonatal tetanus occurs in newborn infants born to unimmunized women following infection by *C. tetani* (most commonly at the umbilical cord stump). Cases are associated with overtly unsterile surfaces used in childbirth, delivery personnel untrained in sterile care of the umbilical cord and stump, and particularly with births followed by unhygienic cultural rituals involving the umbilical stump, such as application of herbs, clarified butter, or animal dung.[8,10,51,62] The risk of disease is lowered by avoiding the application of these substances, as well as "clean" delivery practices[63–65] and potentially antibiotic ointment application.[66,67] Training of birth attendants in clean delivery practices (use of soap and water to clean hands, use of clean surfaces and a sterile cutting device) is a major step in not only preventing neonatal tetanus but also reducing other causes of neonatal mortality.[63–65]

Neonatal tetanus can be prevented through transplacental passage of circulating antitoxin from immunized mother to infant, most of which is in the IgG1 subclass.[16,17,68] Although decreasingly, many newborns in the world continue to be susceptible because their mothers have not received two or more doses of tetanus toxoid; it was estimated that even as of 2006, only 69% of pregnant women in developing countries have received at least two recent doses of tetanus toxoid.[40]

7. Pathogenesis and Immunity

7.1. Pathogenesis

Tetanus results when spores inoculated through the epithelium germinate, leading to the production of tetanospasmin and its transport to the CNS. The period of time between an identified acute injury and onset of tetanus signs and symptoms is 3 days to 3 weeks for the majority of cases. In the United States in 1972–2001, the median incubation period in reported cases was 7 days.[49]

Germination is enhanced by anaerobic conditions associated with significant tissue injury and accumulation of lactic acid.[29] Calcium, as present in soil, may increase the likelihood that injection drug injection drug spores germinate because it can increase local necrosis.[69] Toxin injection drug or produced in the subcutaneous tissue appears to enter muscle first; tetanus can be prevented in experimental animal models by treating the muscle with antitoxin prior to subcutaneous administration of toxin.[70]

Once in the muscle, toxin can reach the bloodstream via the lymphatics. Toxin is disseminated hematogenously: studies show that when toxin is injection drug subcutaneously or intramuscularly, it reaches the bloodstream and from there is distributed to tissues. However, the toxin does not cross the blood–brain barrier; toxin gains access to the CNS by neuronal transport.[70,72–74] Toxin gains entry to the nerve by binding to lipid raft microdomains containing specific polysiagangliosides and glycoproteins at the motor end plates of muscle nerves[75] and is transported to the ventral horns of the spinal cord or motor nuclei of cranial nerves. Transynaptic transport of intact toxin allows transfer to inhibitory neurons in the spinal cord and wider dissemination within the CNS. Different portions of the heavy chain of tetanospasmin have properties necessary for the separate steps of neuron receptor binding, internalization, intraaxonal transport, and membrane translocation. Once released at its site of action, the freed light chain is an endopeptidase that cleaves a synaptic vesicle membrane protein necessary for neurotransmitter release.[35,74,76]

By interfering with the release of the inhibitory neurotransmitters glycine and γ-aminobutyric acid from presynaptic inhibitory fibers, the light chain of tetanospasmin prevents inhibition of spinal cord reflex arcs. This allows excitatory reflexes to multiply unchecked and results in the classic spasms of tetanus.[70] In addition, the toxin light chain can impede release of a variety of other neurotransmitters including acetylcholine when binding to and affecting autonomic and somatic nerves.[76] Action at these sites accounts for autonomic dysfunction in cases of severe cases of tetanus and the flaccid palsy of cranial nerves in cephalic tetanus.

7.2. Immunity

Immunity to tetanus does not generally follow disease, since the quantity of toxin that causes illness is usually less than the quantity needed to induce an immune response.[30] Second cases of tetanus have been reported.[19–21,77] Most serosurveys in unimmunized populations fail to find evidence for natural immunity. A few authors reported serosurveys in unimmunized populations, particularly of developing countries, in which some persons had antibodies.[78,79] However, the assays generally used are now known to be nonspecific at low antitoxin levels; additionally, some subjects may have received prior immunizations. Asymptomatic infection/colonization, presumably of the intestine, may very rarely result in the production of antitoxin.[61]

It is generally accepted that a circulating level of antitoxin of 0.01 IU/ml by neutralization assay is the minimum level needed to assure protection against tetanus.[16–18] This comes from experiments both with humans and with animals. Guinea pigs with serum antitoxin levels of 0.01 antitoxin unit (AU)/ml (prior to international standardization of the assay) or higher following active or passive immunization survived challenges with fixed lethal doses of *C. tetani* spores.[80] Looney reviewed animal studies of active immunization that suggested incremental protection at 0.01–0.1 AU/ml.[81] A review by McComb[18] in 1964 reported that clinical tetanus could be prevented in horses by administration of 1,500 IU/ml of antitoxin after acute injury, which corresponded to a serum level of 0.01 IU/ml. Following immunization with tetanus toxoid, Wolters and Dehmel[82] were able to resist challenge in themselves with "2–3 fatal doses" of tetanus spores. They had achieved serum levels of 0.007–0.01 AU/ml. Further evidence that 0.01 IU/ml was protective came from trials to prevent neonatal tetanus. Induction of antitoxin levels of 0.01 IU/ml or higher in a sample of mothers was correlated with protection of infants from neonatal tetanus.[16]

The appropriate minimum protective level of circulating tetanus antitoxin has been challenged by reports of adult and neonatal tetanus patients who had serum levels greater than 0.01 IU/ml at the time they presented with clinical tetanus.[27,31,83] The highest level measured by neutralization assay noted was 0.16 IU/ml. Large-scale production of toxin from heavily necrotic wounds or uptake of toxin through nerve endings in tissue with inadequate circulation may in some instances prevent neutralization of toxin at antitoxin levels of 0.01 IU/ml or above. Whatever the explanation, these data suggest that the 0.01 IU/ml minimum level of protection by neutralization assay cannot be considered absolute.

8. Patterns of Host Response

8.1. Clinical Features in Children and Adults

The reported incubation period for tetanus ranges from 1 day to several months. However, the majority of cases occur within 3 days to 3 weeks after an injury. In the United States, the median incubation period for cases with injury-associated wounds reported between 1972 and 2001 was 7 days and the range was 0–178 days.[49] The incubation period can vary with distance between the wound and the CNS. The longest periods are reported for injuries farthest away from the CNS, while injuries to the head and trunk have the shortest incubation periods.[70,84] Historically, shorter incubation periods have been associated with more severe disease and higher case-fatality,[11,44,85] although this has not been the case in patients recently reported in the United States.[49]

Clinical tetanus can take one of three forms: (1) localized, (2) generalized, and (3) cephalic.[84] Local tetanus, which is uncommon in humans, consists of painful spasms in a confined area around the site of the original injury.[86] The spasms may persist for weeks to months. The prognosis of tetanus that remains localized is excellent; however, localized tetanus can progress to generalized tetanus, which carries a more ominous prognosis. Over 80% of cases of tetanus fit the generalized tetanus category. Patients most often present with trismus (lockjaw), i.e., spasm of the muscles of mastication. Risus sardonicus, the characteristic facial expression, occurs with trismus and spasm of the facial muscles. It consists of raised eyebrows, tight closure of the eyelids, wrinkling of the forehead, and extension of the corners of the mouth laterally. Initial signs may be followed by involvement of multiple other muscle groups, hyperreflexia, and generalized hypertonicity. Tetanospasms, generalized tetanic seizure activity, consist of sudden painful contraction of all muscle groups, resulting in opisthotonos, adduction and flexion at the shoulders, flexion of the elbows and wrists, and extension of the legs. Spasm of the glottis can cause immediate death. Autonomic nervous system abnormalities consisting of arterial hypertension or hypotension, tachycardia, and arrhythmias, among other manifestations are frequently reported in severe cases.[87] Complications can result directly from the actions of the toxin, from spasms, or from chronic debility. Reported death-to-case ratios for generalized tetanus with medical care have varied from 10 to 75%. With good intensive care, mortality should be less than 20%. The greatest mortality occurs at the extremes of age.[10–14,49]

Cephalic tetanus occurs with injuries or lesions of the head and face.[84] It is characterized by short incubation periods, 1–2 days, and by atonic cranial nerve palsies particularly involving nerves III, IV, VII, IX, X, and XII, singly or in combination. Trismus may be present. Cephalic tetanus may progress to generalized tetanus. Of 563 tetanus cases reported in the United States in 1972–2001 with data on clinical presentation, 88% were generalized, 12% were localized, and $<1\%$ were cephalic.[49]

8.2. Clinical Features in Neonatal Tetanus

Tetanus occurring within the first month of life is a form of generalized tetanus. Symptoms of neonatal tetanus generally begin 3–14 days after birth but can occur from 1 to 28 days of age. The illness starts with poor sucking and excessive crying. This is followed by variable degrees of trismus, difficulty swallowing, opisthotonos, and other tetanic spasms. The case-fatality ratio of neonatal tetanus is 10–90% with therapy, depending on the intensity of supportive care.[6,10,11,14] Overall, the EPI of the WHO estimates that 80% of affected infants die in low-income countries.[8]

8.3. Diagnosis

The diagnosis of tetanus is made primarily on clinical grounds. Generalized stiffness, hyperreflexia, trismus, and the characteristic generalized tetanic spasms strongly support the diagnosis. Absence of changes in the state of consciousness or sensory involvement add further support. The epidemiological history can also be helpful. A preceding history of a wound, particularly if contaminated by soil, is suggestive, although not all cases will have such histories. Lack of a history/record of adequate immunization or wound care is typical. Given the high efficacy of a course of tetanus toxoid, a patient with a clinically compatible case who presents with a history of complete primary series of toxoid and maintenance boosters should undergo an exhaustive workup for other potential causes. The diagnosis of tetanus can be reached if this workup fails to identify another cause. Significant rises in circulating antitoxin are not reliably seen in tetanus and cannot be expected to aid in the diagnosis.[30] Testing for antitoxin using ELISA can be performed on a rapid basis to assist in assessment of immune status; absence of circulating antitoxin at 0.10 IU/ml or greater (by classic ELISA) when the patient is first seen supports the diagnosis. In the event of isolation of the organism from a wound, this is strongly supportive.

The differential diagnosis will depend on the clinical signs and symptoms.[84,88] Trismus may be caused by dental caries, tonsillitis, peritonsillar abscesses, parotitis, temporomandibular joint dysfunction, and CNS disturbances other than tetanus. Hyperreflexia may be seen in rabies; however,

rabies is more often associated with changes in the state of consciousness, and the seizures of rabies are more often clonic in contrast to the tonic seizures of tetanus. The history of an animal bite is generally present with rabies but could be present in tetanus. Encephalitis also can result in spasms, but, like rabies, is much more likely to be associated with changes in the state of consciousness. In addition to infections, a variety of poisonings and metabolic conditions can simulate tetanus. Hypocalcemic tetany can cause generalized muscle spasms but is not usually associated with trismus.[89] Strychnine poisoning, which also causes disinhibition of spinal cord reflex arcs, can resemble generalized tetanus clinically.[90] However, strychnine poisoning is usually not associated with muscle rigidity between spasms and is rarely associated with temperature elevations, which are frequent in severe tetanus. Dystonias caused by phenothiazines also should be considered in the differential diagnosis. Finally, hysteria can mimic tetanus, although such patients tend to relax on prolonged observation and their seizure-like activity tends to be clonic rather than tonic.

9. Control and Prevention

Tetanus is an entirely preventable disease. Prevention begins with universal, routine immunization and with appropriate attention toward averting wounds and injuries. A routine immunization program should ensure that the entire population has received a primary series (at least three doses) of tetanus toxoid with booster doses as needed. Substantial health benefits are derived from combined immunization with diphtheria and tetanus toxoids and pertussis vaccine (DTP) in childhood or (Tdap) in adulthood (one-time dose) or diphtheria toxoid (Td) otherwise in adulthood. Vaccination coverage is high in the United States, with 92% of children 19–35 months of age having received four or more doses of a tetanus toxoid-containing vaccine[91] and 96% of children entering school.[92] It has been estimated that since 1990, more than 70% of target children in the world had received three doses of DTP in the first year of life annually; current estimates are approximately 80%.[40]

Once injuries occur, efforts should be made to prevent contamination with spores and to mitigate those conditions that predispose to germination of spores. Wounds should be carefully cleaned and surgically debrided when necessary to remove devitalized tissue, which can serve as a nidus for infection, followed by tetanus toxoid (and tetanus immune globulin, when needed).[93,94] Since neonatal tetanus is the major worldwide cause of tetanus morbidity and mortality, continued attention must be paid to covering umbilical cord stumps with sterile or uncontaminated dressings. Training of midwives in proper sterile techniques has been demonstrated to reduce the incidence of neonatal tetanus substantially (although not as effectively as immunization of the mother) as well as result in declines in neonatal mortality due to causes other than tetanus.[63–65]

Immunization histories for cases in the United States in 1998–2000 were verified; the immunization status was known for 38% (49) of the 129 nonneonatal tetanus cases reported.[48] Twenty (15%) of the 129 cases had received at least a primary series (i.e., three or more doses) of tetanus toxoid before onset of tetanus; only eight reported that the last dose of the primary series or booster dose of toxoid was received less than 10 years before the illness. Of the 90 patients in 1998–2000 with tetanus following acute wounds and available medical history, 33 (37%) obtained medical care for the injury; a tetanus toxoid-containing vaccine was given as prophylaxis in wound management to 20 (61%) of these and TIG was given to only 3 although the vast majority were apparently eligible. Thus, virtually all cases of tetanus could be prevented with routine immunization and appropriate wound management.

9.1. Passive Immunization

Although animal models suggest that prompt passive immunization is protective against the development of tetanus following injury, there is limited information in humans; appropriately controlled trials have not been performed. Passive immunization with equine antitoxin for treatment and for prophylaxis following wounds became common practice in World War I, with a decrease in wound-associated tetanus at the same time that other improvements in wound care were becoming common practice.[85] Passive immunity conferred by equine antitoxin is of limited duration. The half-life of refined equine antitoxin in humans is less than 2 weeks and may be shorter in some individuals.[95] A major disadvantage is the risk of immediate hypersensitivity reactions or serum sickness.[96]

Tetanus immune globulin (TIG) is a human antibody preparation prepared by cold-ethanol fractionation of the plasma of hyperimmunized adults. TIG was introduced in the early 1960s and was found to have a fairly constant half-life of 28 days in humans.[18] Allergic and serum sickness reactions to equine antitoxin, along with its shorter half-life, made TIG more attractive for passive immunization. TIG has been shown not to pose a risk of hepatitis (B or C) transmission. TIG and other purified immune globulins pose no risk of human immunodeficiency virus (HIV) transmission, since donors are screened to be at low risk, serum is screened for antibody to HIV prior to serum pooling, and, most important, cold-ethanol fractionation inactivates HIV.[97] As an added

safeguard against the possible transmission of hepatitis C virus, the Food and Drug Administration (FDA) is working with the manufacturers to include an additional inactivation/removal step. It is distributed at a concentration of 250 IU/ml in 1-ml vials. Even in the developing world, TIG is beginning to supplant equine antitoxin as it becomes more widely available. Tetanus toxoid is always given when TIG is given to induce persistence of immunity beyond 28 days in those who received a dose or more of toxoid in the past and to initiate active immunization in those without any prior exposure.[98] In contrast to equine antitoxin, the currently licensed TIG products in the United States should never be administered intravenously, because of aggregates. It is intended solely for intramuscular use.

9.2. Active Immunization

Tetanus toxoid is one of the best immunogens available today. A primary series will induce protective levels of circulating antitoxin in virtually 100% of recipients.[16,99] Protective levels usually last at least 10 years and in the majority will be present even up to 25 years after the last dose.[100]

9.2.1. Production and Testing of Tetanus Toxoid. To produce toxoid, *C. tetani* is cultured in large-capacity fermentors in liquid medium free of allergenic substances. The culture filtrate is precipitated with methanol or ammonium sulfate to purify partially extracellular toxin. Toxin is further purified and detoxified with 40% formaldehyde at 37°C. By WHO standards, the final product should contain 0.5% formaldehyde or less. In the United States, minimum requirements stipulate a residual formaldehyde content of 0.02% or less. A single dose of adsorbed toxoid must contain less than 1.25 mg of aluminum. Tetanus and Diphtheria Toxoids and Acellular Pertussis Vaccine, Adsorbed (For Adult Use) (Tdap) products used in the United States, and some preparations of Tetanus and Diphtheria Toxoids, Adsorbed (For Adult Use) (Td), are either thimerosal free or contain only trace amounts ($< 0.00012\%$) from the manufacturing process. Multiple-dose packaging includes 2-phenoxyethanol as preservative, which is present in some single-dose preparations. Some Td products and adsorbed tetanus toxoid multiple-dose preparations contain 0.0033–0.01% thimerosal as preservative (as does the licensed but generally unavailable fluid toxoid).

Potency is determined by animal bioassays: for the fluid preparation, immunized guinea pigs are tested for survival after a toxin challenge; for precipitated toxoid, a serum pool from immunized guinea pigs must exceed 2 IU/ml of tetanus antitoxin. The toxoid content of commercial products is assessed by flocculation; this measure of toxoid protein content (Lf) does not equate directly with immunogenicity as measured by potency in guinea pigs. Adsorbed products available in the United States have a content of 4–10 Lf per dose; fluid products contain 4–5 Lf.

Tetanus toxoid is available in several preparations: Diphtheria and Tetanus Toxoids and Pertussis Vaccine Adsorbed (whole-cell DTP; no longer used in the United States or most industrialized countries; also referred to as DPT outside the United States), Diphtheria and Tetanus Toxoids and Acellular Pertussis Vaccine, Adsorbed (DTaP), and Diphtheria and Tetanus Toxoids Adsorbed (For Pediatric Use) (DT) used in infants and children under 7 years of age. Universal use of DTaP (or DTP where relevant) in infancy and childhood is recommended unless there are contraindications to pertussis vaccine. DTaP is also licensed with other antigens: Haemophilus influenzae type b (Hib) conjugate vaccine, hepatitis B (Hep B), and/or inactivated poliovirus vaccine (IPV) (available as DTaP-Hib, DTaP-Hep B-IPV, and DTaP-Hib-IPV). Td is for use in persons 7 years of age and older; it contains less diphtheria toxoid (2 Lf or less) than the pediatric preparation (over 10 Lf). Td is the preferred preparation for tetanus prophylaxis in adults under all circumstances because the vast majority of adults in need of tetanus toxoid are likely to be susceptible to diphtheria. In the United States, adsorbed (solitary) tetanus toxoid and fluid tetanus toxoid are produced by a single manufacturer for use in persons 7 years of age and older; the latter is only available in limited quantities. In 2005, two Tdap products (reduced content of pertussis antigens and reduced diphtheria toxoid as compared to the pediatric preparation [DTaP]) were licensed for one-time use in persons 10–18 years of age (BOOSTRIX®, GlaxoSmithKline Biologicals, Rixensart, Belgium) and 11–64 years of age (ADACEL®, sanofi pasteur, Inc., Swiftwater, Pennsylvania), depending on the respective product, for protection against tetanus, diphtheria and pertussis; these products can be used in wound prophylaxis if indicated.

In the United States, aluminum hydroxide or aluminum phosphate is used as an adjuvant. These salts allow an adequate immune response after fewer doses of toxoid than with the fluid preparation.[101] Since fluid and adsorbed preparations do not differ substantially with regard to adverse events, adsorbed toxoid is preferred because it confers protective levels of antitoxin for a longer period of time.[101,102] Response to either form of toxoid as a booster dose is equally brisk. In combined active–passive immunization, TIG does not substantially alter the response to adsorbed toxoid as it does with fluid toxoid.[98,103] In some countries other than the United States, a calcium phosphate adsorbed product is also available. The adsorbed toxoid is administered intramuscularly; fluid preparations can be given subcutaneously. Either can be given by jet-injector.

Table 1. Recommendations for Primary Immunization and Booster Doses with Tetanus Toxoid by Age at Beginning Immunization, United States, 2008*

	Age group			
	<1 year	1–6 years		≥7 years
Vaccine	DTaP* or DT+	DTaP*	DT+	Td/Tdap‖
Interval before				
Dose 1	First visit++	First visit	First visit	First visit
Dose 2	1–2 months	1–2 months	1–2 months	1–2 months
Dose 3	1–2 months	1–2 months	6–12 months	6–12 months
Dose 4	approximately 1 year	approximately 1 year	–	–
Boosters	–§	–§	–¶	–‖

* DTaP is the pertussis vaccine preparation for all doses in the series in the United States. Whole-cell DTP is an acceptable alternative throughout the world. Combination DTaP preparations available in the United States include DTaP-HepB-IPV for doses 1–3 and DTaP-Hib for dose four in the series only. A DTaP-Hib-IPV formulation is under review for licensure at the time of publication. See text for details and product descriptions.
+ DT for those with contraindications to pertussis vaccine.
‖ For primary immunization of persons 10–11 years of age and over, one of the three primary series doses (preferably the first) should be Tdap. For persons receiving three doses Td at age 7–10 years, booster dose of Tdap is indicated when aged 11–18 years; an interval of at least 5 years between Td and Tdap is encouraged, but shorter intervals can be used. Booster dose of Td is indicated every 10 years thereafter. Tdap should replace a single dose of Td for adults aged <65 years who have not previously received a dose of Tdap (either in the primary series, as a booster, or for wound management). Only one of two Tdap products (ADACEL® [sanofi pasteur, Swiftwater, Pennsylvania]) is licensed for use in adults. If the person is pregnant and received the last Td vaccination >10 years previously, administer Td during the second or third trimester; if the person received the last Td vaccination in <10 years, administer Tdap during the immediate postpartum period. A one-time administration of 1-dose of Tdap with an interval as short as 2 years from a previous Td vaccination is recommended for postpartum women, close contacts of infants aged <12 months, and all health-care workers with direct patient contact. In certain situations, Td can be deferred during pregnancy and Tdap substituted in the immediate postpartum period, or Tdap can be given instead of Td to a pregnant woman after an informed discussion with the woman.
++ First visit generally at 2 months of age.
¶ Dose 4 of DT indicated at 4–6 years of age unless dose 3 administered at ≥4 years of age. In this instance, dose 4 is not needed. Booster dose of Td is indicated at 11–12 years of age and booster doses of Td are every 10 years thereafter.
§ Dose 5 of DTaP (DTP) or DT indicated at 4–6 years of age unless dose 4 administered at ≥4 years of age. In this instance, dose 5 is not needed. Booster of Tdap is indicated at 11–12 years of age and boosters of Td every 10 years thereafter.
DT, diphtheria and tetanus toxoids for pediatric use; DTaP, diphtheria and tetanus toxoids and acellular pertussis vaccine; DTP, diphtheria and tetanus toxoids and pertussis vaccine; Td, tetanus and diphtheria toxoids for adult use, Tdap, tetanus toxoid reduced diphtheria toxoid and acellular pertussis vaccine for use in adolescents or adults.

Preparations should be stored at 2–10°C and generally have a 2-year expiration date. Higher ambient temperatures for 3 days or under do not reduce the potency of the toxoid. Freezing reduces potency, particularly when the toxoid is a component of DTP.[104]

9.2.2. Use of Tetanus Toxoid. Most immunization schedules in developed countries call for two or three doses in the first year of life followed by a reinforcing dose 6 months to 1 year afterward.[105–107] The routine schedule for tetanus immunization in the United States is given in Table 1. In children less than 7 years old, tetanus toxoid is usually combined with diphtheria toxoid and pertussis vaccine as DTaP in various potential combinations with other vaccines. When given as DTaP, three doses starting at 6 weeks to 2 months of age are indicated 1–2 months apart followed by a fourth dose approximately 6–12 months after the third dose. If pertussis vaccine is contraindicated, DT is indicated. In the first year of life, the schedule is identical to the DTaP schedule if substituted. However, if beginning in the second year, only three doses of DT are required for primary immunization: two doses 1–2 months apart followed by a third dose 6–12 months after the second. For developing countries, WHO, with its emphasis on infants and child survival, recommends a total of three doses of DTP early in the first year of life; booster doses can be considered depending on the resources available (Table 2). Ideally, all individuals should receive a total of five doses of tetanus toxoid-containing vaccine in childhood, followed by a sixth

Table 2. Recommendations of the World Health Organization for Immunization with Diphtheria–Tetanus–Pertussis (DTP) and Tetanus and Diphtheria Toxoid (Td) Vaccines Required to Obtain Long-Term Protection Against Tetanus, 2008*

Recommended schedule beginning in infancy	DTP	DTP	DTP	Td	Td	Td
	Before age one or as early as possible after age 6 weeks, with >=4 week intervals			e.g. 4–7 years	e.g. 12–15 years	Early adulthood
Adolescents and adults with no previous immunization	Td	Td	Td	Td	Td	
	As early as possible	At least 4 weeks later	At least 6 months later	At least 1 year later	At least 1 year later	
Pregnant women with no previous immunization (or unreliable immunization information)	Td	Td	Td	Td	Td	
	As early as possible in first pregnancy	At least 4 weeks later	At least 6 months later, or in next pregnancy	At least 1 year later, or in next pregnancy	At least 1 year later, or in next pregnancy	
Pregnant women with 3 childhood DTP doses	Td	Td	Td			
	As early as possible in first pregnancy	At least 4 weeks later	At least 1 year later			
Pregnant women with 4 childhood DTP doses	Td	Td				
	As early as possible in first pregnancy	At least 1 year later				
Supplementary immunization activities in high-risk areas (women of childbearing age)	Td	Td	Td	Td	Td	
	During round 1	During round 2, at least 4 weeks after round 1	During round 3, at least 6 months after round 2	At least 1 year later, (e.g. in next pregnancy)	At least 1 year later, or in next pregnancy

dose in early adulthood to provide added assurance of protection throughout the childbearing years (Table 2).[107]

Protective levels of tetanus antitoxin can be achieved with schedules starting in the newborn period. However, in most countries immunization rarely starts before 2 months of age. In the past, it was thought that passively transferred maternal antitoxin would not interfere with the immune response of the infant. However, most of these studies were done before women had been routinely immunized either as children or as adults. More recent studies in the United States demonstrate that substantial proportions of infants have levels of circulating antitoxin at the time of initiating the DTP series, suggesting that the issue of interference should be reconsidered.[108,109] The need for three doses in the first year of life was supported by a report by Barkin,[108] who demonstrated that substantially higher levels of antitoxin are achieved after three doses in the first year of life compared to two doses. The height of the antitoxin response is directly related to the age at completion of the third dose. There is no good evidence that intervals of 2 months for the first three doses offer any advantage over 1 month. All achieve protective levels regardless of schedule, although antitoxin levels are higher after the 2-month interval probably because these children are older at the time they complete their three-dose schedule. Nevertheless, by the time the fourth dose is indicated (approximately 1 year after the third dose), antitoxin levels are comparable in both groups. Preterm infants appear to respond similarly at the same chronological age as term infants.[105,110]

Unimmunized children 7 years of age or older and adults require a three-dose primary series with two doses 1–2 months apart followed by a third dose 6–12 months after the second (Table 1).[105,106] In the United States, the Td adult preparation that contains a decreased amount of diphtheria toxoid is used (or a single use in adolescence/adulthood of an appropriate Tdap product). The immune response to tetanus

toxoid tends to decrease somewhat with increasing age. In comparative studies, children tend to achieve higher levels of antitoxin than do adults. The elderly tend to make a poorer response to toxoid than do younger adults.[111,112] Nevertheless, almost all children and adults will achieve protective titers after a three-dose primary series.

In developing countries, immunization of adults is directed primarily for pregnant women in order to prevent maternal and neonatal tetanus. Induction of protective levels in mothers provides protection from neonatal tetanus by transfer of antitoxin across the placenta.[8,16,113,114] A minimum of two doses at least 1 month apart has been recommended by the EPI for pregnant women with the last dose at least 2 weeks prior to the estimated date of delivery (Table 2). However, difficulties in finding and vaccinating pregnant women and a desire to eliminate maternal as well as neonatal tetanus have led to efforts in some places to vaccinate all women of childbearing age. In addition, vaccination with only two doses is less than optimally effective and does not provide long-term protection. One dose provides little chance of protection.[8] The schedule listed in Table 2, which recommends a total of five tetanus toxoid doses with the third at least 6 months after the first, has been adopted by the EPI in hopes of inducing sustained levels of circulating antitoxin in all women for life.[107]

Where immunization programs are sufficiently developed, WHO currently recommends that all individuals ideally should receive a total of five doses of tetanus toxoid-containing vaccines in childhood followed by an additional dose in adulthood. Td is recommend at approximately age 4–7 years and again in adolescence (e.g., age 12–15 years) (Table 2). In addition, Td should replace tetanus toxoid for adult vaccination.[107]

After a three-dose primary series, circulating antitoxin remains at protective levels for years. Studies in Denmark demonstrate that 96 and 72% of subjects had levels $\geq$0.01 IU/ml at 13–14 and $\geq$25 years, respectively, after the third dose of a product containing 7–12 Lf.[100] Based on these studies and others, immunization advisory bodies in the United States have recommended routine boosters of a tetanus toxoid-containing preparation every 10 years.[105,106] The booster response is not impaired even with intervals of 20 or more years since the last dose.[115] There is no need to restart a primary series if the schedule has not been followed or booster doses have been missed. Instead, prior doses should be counted and the remaining doses given to finish the three-dose primary series. Missed boosters can be ignored. In the United States, a preschool booster of DTaP is recommended at 4–6 years of age primarily to ensure immunity to pertussis in young schoolaged children. Doses of tetanus toxoid are recommended in the United States at 11–12 years of age and every 10 years thereafter. Since the introduction of Tdap, a single booster is recommended at 11–12 years of age, or for one of the subsequent booster doses in adults when indicated.[116,117]

Tetanus in the United States continues to be a disease primarily of older adults who are also at highest risk for tetanus mortality. To decrease this remaining tetanus burden, the Advisory Committee on Immunization Practices (ACIP) and other advisory committees recommend that for patients aged 50 years, health-care providers annually administer influenza vaccine, and on first contact, should review adult vaccination status, administer tetanus and diphtheria toxoid as indicated, and determine whether a patient has one or more risk factors that indicate the need to receive pneumococcal or other vaccination. In the National Health Interview Survey of 1999, 63% of males 50–64 years of age and 50% $\geq$65 years of age reported having received a tetanus toxoid dose within the prior ten years; among females, the proportions were 51 and 36%, respectively.[118] This compares to 67% of males $\geq$65 years of age who reported receiving influenza vaccine in the previous 12 months and 65% of females.

9.2.3. Adverse Events. Reports of local reactions following tetanus toxoid vary greatly. In general, 50–85% of recipients of booster doses of adsorbed toxoid experience pain or tenderness at the injection site. While 20–30% experience edema and erythema,[119,120] marked swelling occurs in less than 2%. Controlled studies suggest that minor swelling or pain may occur more frequently in individuals receiving Td than among those receiving tetanus toxoid; however, substantial differences in marked swelling have not been demonstrated.[120] Several studies have found that the greater the preexisting antitoxin level, the higher is the incidence of local reactions, which generally begin within 2–8 h of an injection.[119,121,122] There have been reports of massive local swelling, particularly in persons with a history of multiple successive booster doses of toxoid. Such persons are typically found to have high serum antitoxin levels, likely leading to the formation of immune complexes with the deposited toxoid (Arthus reaction).[121,123] Thus, frequent boosters of tetanus toxoid in wound management are discouraged.

Fever can accompany a local response, particularly a marked local reaction.[120] Overall, booster doses of Td are associated with fever in 0.5–7%, with temperature over 39°C being rare.[122,124] Headache and malaise are unusual.

In 1994, the Institute of Medicine published an extensive review of adverse events following vaccination.[125] This review suggested that the evidence favors a causal relation between tetanus toxoid administration and Guillain–Barré syndrome, as well as brachial neuritis. The evidence was considered insufficient to assess a causal relationship between tetanus toxoid and mononeuropathy. Subsequent

population studies do not support a causal role for tetanus toxoid in GBS.[126]

Anaphylactic reactions to purified tetanus toxoid appear to be rare.[125] In the United States, passive surveillance in 1991–1995 for serious allergic reactions including laryngospasm, bronchospasm, or anaphylaxis yielded a rate of 1.6 serious allergic reactions reported per million doses of publicly distributed Td.[127] Skin testing has been urged in management of patients with a history suggestive of such a reaction.[128] Interpretation of some skin test results should take into account some expected nonspecificity of skin test reactions, particularly since only adsorbed products are widely available.

9.2.4. Wound Management. An individual who presents for medical care with any type of wound should be evaluated for potential tetanus prophylaxis. Removal of foreign bodies and debridement of devitalized tissue in a timely fashion are imperative; if necessary, drainage and irrigation should be performed.[93,94] Recommendations for the use of tetanus toxoid and TIG in the United States for tetanus prophylaxis in the management of wounds have been made by the ACIP and agree with those of the American Academy of Pediatrics and the Committee on Trauma of the American College of Surgeons.[93,105,106] The recommendations of the ACIP are given in Table 3.

Although any wound can potentially give rise to tetanus infection, uncomplicated wounds are considered to have a low likelihood both of contamination by tetanus spores and of leading to an environment that would support germination of spores. For persons with this category of wounds, Td or Tdap is recommended if the patient has received less than three doses of adsorbed toxoid in the past or it has been more than 10 years since the previous toxoid dose; TIG administration is not necessary. Such individuals respond briskly to subsequent doses of tetanus toxoid generally within 4 days.[129]

Most patients who had received three doses of fluid toxoid in the past, and rarely individuals who received three doses of adsorbed toxoid, may have circulating antitoxin levels less than 0.01 IU/ml after 5 years.[16,130] Therefore, it is recommended that persons with wounds that are of higher risk of contamination (wounds that are neither minor nor clean) receive a dose of toxoid if more than 5 years have elapsed since the last dose. Because fluid toxoid is no longer used for tetanus prophylaxis in the United States, the rationale for this recommendation is becoming less relevant. Individuals with wounds that are neither minor nor clean are also potential candidates for simultaneous passive immunization with TIG if the immunization history indicates fewer than three toxoid doses. When administered at a separate site, TIG does not interfere with the immune response to adsorbed tetanus toxoid. An intramuscular dose of 250 units (1 ml) is recommended by the AAP and ACIP;[105,106] a dose of 500 units is recommended by some for patients with more serious wounds, who presented with delay or who weigh more than the average adult.[93,131,132]

Based on the history of care, almost all of the tetanus cases with wounds in the United States might have been prevented with appropriate wound management. Of the 992 patients in the United States during 1972–1989 with acute wounds, tetanus toxoid was given as prophylaxis in wound management to only 29%; of these, 77% received toxoid within 3 days of injury.[49] Tetanus toxoid alone is not sufficient in patients who have never received at least a three-dose primary series. Most of these individuals were also potential candidates for, but did not receive, TIG. Thirty-three percent of the 992 patients with acute wounds reportedly underwent debridement after injury and before onset of tetanus symptoms. Of these 327 patients, 93% did not receive the recommended Td with or without TIG based on their individual immunization histories. Although underadministration of tetanus prophylaxis following wounds is the predominant

Table 3. Summary Guide to Tetanus Prophylaxis in Routine Wound Management, United States, 2008

History of adsorbed tetanus toxoid (doses)	Clean, minor wounds		All other wounds*	
	TTCV+	TIG	TTCV+	TIG
Unknown or <3	Yes	No	Yes	Yes
≥3**	No §	No	No†	No

* Including, but not limited to, wounds contaminated with dirt, feces, soil, saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns and frostbite.

+ TTCV, Tetanus toxoid-containing vaccine. For children <7 years old, DTaP (DT, if pertussis vaccine is contraindicated) is preferred to TT alone. Whole-cell DTP may be used instead of DTaP as indicated, or in other countries. For children 7–9 years of age, Td is preferred to TT alone. Tdap is preferred to Td for persons aged 10–64 years who have never received Tdap, and Td is preferred to TT for persons aged 10–64 years who received Tdap previously or when Tdap is not available. Only one of two Tdap products (ADACEL® [sanofi pasteur, Swiftwater, Pennsylvania]) is licensed for use in adults. (If TT and TIG are both used, Tetanus toxoid adsorbed rather than tetanus toxoid for booster use only [fluid vaccine] should be used).

** If only 3 doses of *fluid* toxoid have been received, then a fourth dose of toxoid, preferably an adsorbed toxoid, should be given.

§ Yes, if more than 10 years since last dose.

† Yes, if more than 5 years since last dose. (More frequent boosters are not needed and can accentuate side effects.)

DT, diphtheria and tetanus toxoids for pediatric use; DTP, diphtheria and tetanus toxoids and pertussis vaccine; Td, tetanus and diphtheria toxoids for adult use; TT, tetanus toxoid.

(3) Centers for Disease Control and Prevention. Preventing tetanus, diphtheria, and pertussis among adults: use of tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine. Recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR 55(No. RR-17):1–33, 2006.

history in reported tetantus patients with wounds, underadministration of tetanus prophylaxis following wounds overall appears to be the exception rather than the rule. Three studies indicated that when patients with wounds sought care in the United States, 1–35% received less than the recommended prophylactic measures of Td with or without TIG indicated by their wound and immunization history and 8–17% received more than recommended.[133–135]

9.3. Antimicrobials

As a substitute for or adjunct to equine antitoxin prior to wide availability of TIG, antibiotics were once frequently used for tetanus prophylaxis in wound management. Antimicrobials may cause complications and have been known to fail. Antimicrobials have not been proven to have superior or equal efficacy to antitoxin and are not currently recommended for tetanus prophylaxis.[94,136] There are some data to suggest antibiotic ointment application to the umbilical stump may prevent neonatal tetanus.[66,67]

9.4. Summary

Tetanus is an toxin-mediated infectious but noncommunicable disease. The spores of *C. tetani* are ubiquitous in nature and when deposited under the epithelium of the skin can germinate, given anaerobic conditions, leading to the production of tetanospasmin. The toxin travels to the CNS along peripheral nerves and causes disease by presynaptic interference with release of inhibitory neurotransmitters, leading to disinhibition of spinal cord reflex arcs and accumulation of excitatory stimulation. This results in the tetanospasm, a generalized muscular spasm. Death-to-case ratios vary from 10 to 75%, depending on care, immunization status, age, and other risk factors.

The disease can be prevented by appropriate attention to routine immunization and wound management. Tetanus toxoid is one of the most effective immunogens known, with essentially all recipients of a primary series protected for at least 5–10 years and often 25 years. Since wounds are the most frequent predisposing cause of tetanus outside the neonatal period, special attention should be paid to (1) wound cleansing and debridement to remove both spores and devitalized tissue and (2) providing protective levels of circulating antitoxin including both passive immunization to achieve protection rapidly and active immunization to increase levels rapidly in previously primed persons. Completion of a primary series will lead to sustained protection and prevent cases not associated with acute injuries; appropriate routine immunization would circumvent the need for passive immunization following wounds. It is particularly important to review the immunization history of elderly patients to ensure completion of primary immunization and routine boosting.

Tetanus can occur within the first month of life in infants born to unimmunized women followed by infection by *C. tetani.* Cases are often associated with unsterile conditions of childbirth and with unhygienic cultural rituals involving the umbilical stump. Although neonatal tetanus was once responsible for an estimated 1.2 million deaths per year, because of the increasing immunization coverage of pregnant women and women of childbearing age, targeted mass immunization in high-risk populations, and the increasing prevalence of clean deliveries, its annual burden has been reduced to less than 180,000 neonatal tetanus deaths. Maternal and neonatal tetanus is targeted for elimination through continued efforts to reach all populations.

10. Unresolved Problems

Although the disease is becoming uncommon, the major problem in tetanus prevention today continues to be the difficulty in delivering routine immunization to those in need. In 2004, an estimated 40 million pregnant women in developing countries were still in need of immunization against birth-associated tetanus and an estimated 180,000 infants die of neonatal tetanus annually.[41,107] The vast majority of these deaths occur in countries with limited health services where most women do not have ready access to prenatal care. The goal of maternal and neonatal tetanus elimination made in 1989 was renewed in 2000 with a target of 2005; the advances made since 2000 have been primarily because of campaigns to vaccinate pregnant women in the highest risk areas.[107,137] In all developing countries, most children are born outside of a hospital; in the countries at highest risk, there needs to be greater emphasis on prenatal care, attended delivery and potentially vaccination of women of childbearing age if maternal and neonatal tetanus is to be eliminated as a significant public health problem. Every contact of a susceptible female of childbearing age with the health-care system could be taken as an opportunity to update her tetanus immunization status. In addition, there is a continuing challenge to sustain progress made in immunizing women and in increasing the prevalence of clean deliveries.

In 1999, WHO instituted a validation process to monitor progress toward the goal of sustainable elimination of maternal and neonatal tetanus for each country at risk.[41] Using that process, 11 of the 57 countries remaining at risk

for maternal and neonatal tetanus in 1995 have been validated as having eliminated it. As of January 2008, more than 145 countries and areas have succeeded in reaching the WHO definition of elimination. Based on this progress, WHO estimates that an additional eight countries will reach and validate elimination by the end of 2008.[138]

Routine immunization remains incomplete; about 27 million children a year did not complete their primary tetanus immunization series.[107] With strengthening of child immunization services and with booster immunizations becoming progressively routine (to ideally vaccinate every child five times by the age of 15 years), tetanus in all ages will become increasingly rare.

In the United States, the limited remaining morbidity and mortality from tetanus are predominantly in the elderly who have never completed primary immunization. Serological surveys suggest that substantial majorities of these populations lack protection.[22] Greater efforts are needed by practitioners to review the immunization status of their elderly patients and offer Td as needed.

Proper wound management could still prevent a significant proportion of current tetanus cases. All health-care providers, particularly in emergency departments, need to be familiar with the recommendations for tetanus prophylaxis in wound care, including administration of passive immunization when applicable to persons who are unimmunized or whose immunization status is unknown. However, since chronic conditions and mild injuries are also associated with tetanus, the best approach to tetanus prevention is universal routine immunization and boosting.

CHAPTER 39

Toxic Shock Syndrome (Staphylococcal)

Arthur L. Reingold

1. Introduction

Staphylococcal toxic shock syndrome (TSS) is an acute, multisystem febrile illness caused by *Staphylococcus aureus*. A similar illness caused by group A streptococcal infections is discussed in Chapter 34. The accepted criteria for confirming a case of TSS include fever, hypotension, a diffuse erythematous macular rash, subsequent desquamation, evidence of multisystem involvement, and lack of evidence of another likely cause of the illness (Table 1).

2. Historical Background

TSS was first described as such in 1978 by Todd et al.[1] However, cases of what we now believe to have been TSS have been reported in the medical literature since at least 1927 as "staphylococcal scarlet fever" or "staphylococcal scarlatina."[2,3] In addition, a number of patients reported in the medical literature in the 1970s as having adult Kawasaki disease probably had TSS.[4] The association between illness and focal infection with *S. aureus* was, by definition, apparent in early reports of staphylococcal scarlet fever, but was reinforced by the findings of Todd et al.[1] and later by the findings of other investigators.[5,6]

TSS achieved notoriety in 1980 when numerous cases were recognized and an association between illness (in women), menstruation, and tampon use was demonstrated.[7,8] While the early case reports of staphylococcal scarlet fever and the report by Todd et al.[1] clearly showed that TSS occurred in small children, men, and women who were not menstruating, most (but by no means all) of the cases initially recognized and reported in late 1979 and early 1980 were in menstruating women,[8–10] leading to the frequent misperception among the general public and many physicians that TSS occurred only in association with tampon use (hence, "the tampon disease"). This misperception undoubtedly led to subsequent biases in the diagnosing (and probably reporting) of TSS cases. However, later studies designed to eliminate such biases have shown that TSS does, in fact, occur disproportionately in menstruating women,[11,12] while case-control studies demonstrating an association between the risk of developing TSS during menstruation and tampon use preceded (indeed, led to) the introduction of bias concerning the relationship between tampon use and menstrual TSS.[5,6]

Follow-up studies demonstrated that the risk of developing tampon-related menstrual TSS varies with the absorbency, chemical composition, and oxygen content of the tampon,[13–16] although the relative importance of these and other tampon characteristics in determining that risk remains uncertain. As a result of both epidemiological and in vitro laboratory studies, the formulation of available tampons changed dramatically in the early 1980s, such that absorbencies were substantially lower and chemical composition was less varied across brands and styles. Studies in the late 1980s demonstrated that the incidence of TSS, particularly menstrual TSS, rose and fell in parallel with the absorbency of tampons,[17] but that the risk of developing menstrual TSS continued to vary directly with tampon absorbency, despite the changes in tampon formulation.[18]

Table 1. Case Definition of Toxic Shock Syndrome

Fever: temperature $\geq$ 38.9 °C (102 °F)
Rash: diffuse macular erythroderma
Desquamation: 1–3 weeks after onset of illness
Hypotension: systolic blood pressure $\leq$ 90 mmHg for adults or below fifth percentile by age for children under 16 years of age, orthostatic drop in diastolic blood pressure $\geq$ 15 mmHg from lying to sitting, orthostatic syncope, or orthostatic dizziness
Multisystem involvement: three or more of the following:
Gastrointestinal: vomiting or diarrhea at onset of illness
Muscular: severe myalgia or creatine phosphokinase level at least twice the upper limit of normal for laboratory
Renal: blood urea nitrogen or creatinine at least twice the upper limit of normal for laboratory or urinary sediment with pyuria ($\geq$ 5 leukocytes per high-power field) in the absence of urinary tract infection
Hepatic: total bilirubin, serum aspartate transaminase, or serum alanine transaminase at least twice the upper limit of normal for laboratory
Hematologic: platelets $<$ 100,000 mm^3
Central nervous system: disorientation or alterations in consciousness without focal neurological signs when fever and hypotension are absent
Negative results on the following tests, if obtained:
Blood, throat, or cerebrospinal fluid cultures (cultures may be positive for *Staphylococcus aureus*)
Rise in titer to Rocky Mountain spotted fever, leptospirosis, or rubeola

3. Methodology

3.1. Sources of Mortality Data

Mortality rates for TSS have not been reported directly, but can be estimated from reported incidence rates and case-fatality ratios.

3.2. Sources of Morbidity Data

Surveillance for TSS began in a few states in late 1979 and in other states and nationally in early 1980. Since that time, TSS has been made a reportable disease in most states. However, the level of intensity of surveillance activities has varied markedly between and within states. Thus, a few states established active surveillance for TSS for brief periods of time, while others did little to stimulate the diagnosis and reporting of cases. As a result, the completeness of diagnosing and reporting TSS cases undoubtedly has been inconsistent between states and over time. However, data from a national hospital discharge survey indicated that reporting of cases in the 1980s, while incomplete and variable by region, was not biased dramatically insofar as the age, race, sex, or menstrual status of the patients was concerned.[19] Hospital record review studies, in which both diagnosed and previously undiagnosed cases of TSS were ascertained in a consistent fashion, so as to minimize or eliminate both diagnostic and reporting biases, also have been conducted.[11,12,17,20,21] These studies demonstrated that, by and large, the patient characteristics and temporal trends observed in data collected through the largely passive network of TSS surveillance reflected true variation in the incidence of TSS by age, sex, race, and menstrual status. These same studies, taken together, demonstrated that at least some of the apparent geographic variation in the incidence of TSS in the United States in the 1980s was real. More recent information concerning the epidemiologic features of TSS comes almost entirely from the passive national surveillance system, as few epidemiologic studies of TSS have occurred since the 1980s.

3.3. Surveys

Numerous small surveys have demonstrated that many asymptomatic individuals carry, in the nasopharynx and/or vagina, strains of *S. aureus* that produce TSS toxin-1 (TSST-1), the toxin believed to be responsible for most TSS cases.[22–26] Similarly, large serosurveys have shown that antibodies to TSST-1 or to a cross-reacting antigen are extremely common.[22,25,27,28]

3.4. Laboratory Diagnosis

3.4.1. Isolation and Identification of the Organism. While recovery of *S. aureus* from the vagina or another site of infection is not one of the criteria of the TSS case definition, it is possible in most TSS cases if appropriate specimens are obtained before antimicrobial therapy is initiated.[5,6,29,30] *S. aureus* grows readily on most standard culture media and is readily identifiable by any clinical microbiology laboratory within 2 or 3 days. Testing of *S. aureus* strains for production of TSST-1, however, is performed in only a few research laboratories. Hence, the results of such testing are not readily available during the acute illness and are not of value in treating patients suspected of having TSS. Furthermore, because both *S. aureus* in general and TSST-1 producing strains of *S. aureus* in particular can be recovered from many patients without the clinical features of TSS and from asymptomatic individuals, microbiological results cannot and do not prove that a given patient has TSS.

3.4.2. Serological and Immunologic Diagnostic Methods. A variety of serological and immunologic techniques have been used to test *S. aureus* strains for production of TSST-1. As noted above, these tests are not available outside a few research laboratories. It is possible to detect TSST-1 in clinical specimens,[31,32] but these assays are not generally available. Antibodies to TSST-1 can be measured using solid-phase radioimmunoassay and other techniques. However, most healthy individuals have

detectable anti-TSST-1 antibodies.[22,25,27,28] Furthermore, some patients with TSS have demonstrable anti-TSST-1 antibodies at the time of onset, and many patients without such antibodies at the time of onset do not demonstrate an antibody rise in response to their illness.[27,33] Thus, testing for anti-TSST-1 antibodies (which is not available except in one or two research laboratories, in any event) is of limited value in confirming the diagnosis of TSS, although it has been argued that the absence of detectable antibodies at the time of onset supports the diagnosis of TSS.

4. Biological Characteristics of the Organism

As noted above, there is convincing evidence that *S. aureus* is the cause of TSS. In patients with menstrual TSS, *S. aureus* can be recovered from the vagina and/or cervix in 95–100% of cases (usually as a heavy growth), but in only 5–15% of healthy control women.[5,24,34–39] In patients with nonmenstrual TSS associated with a focal wound, *S. aureus* is typically the only organism found in the lesion.[29,30] Furthermore, experimental studies demonstrate that TSS-associated *S. aureus* strains can cause a similar illness in rabbits.

Similarly, there is strong evidence that the ability to make TSST-1, previously known as pyrogenic exotoxin C,[40] staphylococcal enterotoxin F,[41] and several other names, is characteristic of, although not universal among, TSS-associated *S. aureus* strains. Thus, 90–100% of *S. aureus* isolates recovered from the vagina, cervix, or used tampon in menstrual TSS cases produce TSST-1, compared with only 10–20% of vaginal or nasopharyngeal isolates from healthy controls.(26,40–43) On the other hand, only 60–70% of *S. aureus* strains recovered from normally sterile sites in patients with nonmenstrual TSS produce TSST-1,[44–46] suggesting that other staphylococcal toxins, particularly staphylococcal enterotoxin B (SEB), are capable of inducing a clinically indistinguishable syndrome. Two studies of historical strains of *S. aureus* demonstrated that the proportion of strains capable of making TSST-1 has changed over time and was generally higher in the mid to late 1970s than in earlier time periods.[42,47] Interestingly, that proportion appears to have declined somewhat in the early 1980s, when the incidence of TSS was peaking. More recent data concerning the proportion of *S. aureus* strains that make TSST-1 have not been published.

TSS-associated *S. aureus* strains also have been characterized phenotypically with respect to a number of other properties, including phage type, antimicrobial susceptibility, resistance to heavy metals, production or activity of various enzymes, and presence of plasmids and bacteriophages. The picture that emerges with regard to these characteristics, while consistent, is by no means invariable or unique. A higher proportion of TSS-related *S. aureus* strains are lysed by phase types 29 and/or 52 (58–82%), as compared to only 12–28% of control strains.[42,43,48] Similarly, TSS-associated strains generally are resistant to penicillin (and ampicillin), arsenate, and cadmium, while being susceptible to β-lactamase-resistant antimicrobial agents, most other commonly tested antimicrobial agents, bacteriocins, and mercury.[6,49,50] Other characteristics that appear to distinguish these strains from other *S. aureus* strains include decreased production of hemolysin, lipase, and nuclease;[49,51] tryptophan auxotypy;[52] decreased lethality in chick embryos;[49] increased pigment production;[53] and increased casein proteolysis.[53] TSS-associated strains also have been reported to be less likely to carry plasmids and more likely to carry lysogenic bacteriophage than control strains. There is controversy over whether or not the gene coding for TSST-1 can be transferred by lysogeny.[54,55]

It should be noted that most of the strains examined in the above studies were recovered from the genital tract in menstrual TSS cases. Thus, the results are not necessarily applicable to *S. aureus* strains associated with nonmenstrual TSS, and there is some evidence to suggest that such strains, recovered from normally sterile sites in patients with nonmenstrual TSS, are less likely to be lysed by phage types 29 and/or 52 than strains from menstrual TSS cases.[44] At the same time, as noted above, they also are less likely to make TSST-1.

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

Carriage of *S. aureus* on the skin and in the nasopharynx and vagina is very common. Numerous cross-sectional studies have demonstrated that 30–40% of individudals carry *S. aureus* in the nasopharynx and 5–15% of women carry *S. aureus* in the vagina.[22–24,34–39] The corresponding figures for TSST-1-producing *S. aureus* are 5–15% (nasopharynx) and 1–5%(vagina). Thus, carriage of *S. aureus* strains believed to be capable of causing TSS is also very common.

In contrast, TSS is a rare disease. After it became a notifiable disease in 1983, the number of cases reported annually in the United States initially ranged from 400 to 500. More recently, approximately 100–150 cases have been reported annually to the Centers for Disease Control and Prevention (CDC).[56] The most reliable estimates of incidence rates come from hospital-based record review studies. In these studies, both diagnosed and previously undiagnosed cases of TSS were ascertained in an unbiased way by reviewing

thousands of medical records of hospitalized patients with one of a long list of discharge diagnoses likely to be indicative of misdiagnosed cases of TSS. In one such study in Colorado, the annual incidence of TSS in women between the ages of 10 and 30 years was 15.8/100,000 in 1980.[12] In a similar study in California, the incidence rate in women between the ages of 15 and 34 years was only 2.4/100,000 in 1980.[11] The incidence rate in men of the same age group in the latter study was consistently less than 0.5/100,000 in all of the years studied.

Initial estimates of the incidence of diagnosed TSS derived from statewide surveillance systems established in late 1979 or early 1980. The states with the most aggressive case-finding methods reported annual incidence rates, at that time, of 6.2/100,000 menstruation women (Wisconsin),[5] 8.9/100,000 menstruating women (Minnesota),[57] and 14.4/100,000 females 10–49 years of age (Utah).[58] An overall estimate of 0.8/100,00 total population of hospitalized, diagnosed TSS in the United States in 1981 and 1982 was derived from a national hospital discharge survey.[19] More recent estimates of the incidence of TSS, based on admittedly incomplete passive surveillance, are even lower.[56] While TSS has been documented in numerous other countries, no estimates of incidence rates for other countries are available.

The discrepancy between the frequency of colonization and/or infection with TSST-1-producing *S. aureus* and the rarity of TSS is thought to be due to the fact that most individuals have detectable anti-TSST-1 antibodies. By age 30 years, more than 95% of men and women have such antibodies.[28] The origin of these antibodies is unknown.

5.2. Epidemic Behavior and Contagiousness

Because TSS increased dramatically in incidence in the United States beginning in 1979 in comparison with previous years,[11,12,20] it would be correct to say that an epidemic of TSS occurred at that time. TSS does not occur, however, in explosive epidemics in the same way that dengue and meningococcal disease do, although strains of *S. aureus* that produce TSST-1 are, like other *S. aureus* strains, transmitted readily by person-to-person spread.

5.3. Geographic Distribution

5.3.1. United States. Cases of TSS have been reported in all 50 states and the District of Columbia, but the incidence of reported cases has varied substantially between states and regions.[9,10,56] Variation in the completeness of diagnosis and reporting of cases undoubtedly accounts for some of the observed differences, but there is substantial evidence that at least some of the observed differences are real. For example, a study of hospital discharge data in which differences in the reporting of cases could not have been a factor showed that the overall annual incidence of hospitalized cases varied by region between 0.24 and 1.43/100,000 in 1981–1982.[19] In this study, however, potentially large differences in the completeness with which TSS cases were diagnosed and different standards for hospitalizing patients suspected of having TSS could not be ruled out. More convincing evidence for true geographic differences in incidence rates comes from the virtually identical hospital record review studies conducted in Colorado and northern California, in which variation in the diagnosing and reporting of cases was largely or completely eliminated.[11,12] As noted above, the incidence of TSS in 1980 in females 10–30 years of age was 15.8/100,000 in Colorado, but only 2.4/100,000 females 15–34 years of age in northern California. However, a prospective study employing active surveillance for TSS in five states (Missouri, New Jersey, Oklahoma, Tennessee, and Washington) and one large county (Los Angeles) showed that in 1986 the incidence of menstrual TSS was in the range of 1/100,000 females 15–44 years of age in all six study areas.[59]

Studies of *S. aureus* strains from the United States show no geographic differences in what proportion make TSST-1.[47] Similarly, anti-TSST-1 antibodies are found in similar proportions of healthy individuals in different parts of the United States.

5.3.2. Other Countries. Documented cases of TSS have been reported from Canada, most of western Europe, Australia, New Zealand, Japan, Israel, South Africa, and elsewhere. No information concerning incidence rates of TSS outside of the United States is available. However, the proportion of cases in other countries associated with menstruation and tampon use appears to be substantially lower than in the United States, in keeping with the fact that tampon use in general is less frequent in other countries and superabsorbent tampons are less widely used.

5.4. Temporal Distribution

Substantial controversy has surrounded the interpretation of observed changes over time in the diagnosis and reporting of TSS cases. Data from the passive national surveillance system suggested that the number of cases began to rise in 1978, peaked in 1980, and then declined and leveled off, with virtually all of the observed differences being due to changes in the number of menstrual TSS cases reported[9,10] (Figure 1). While this pattern was also observed in some individual states employing vigorous case-finding methods

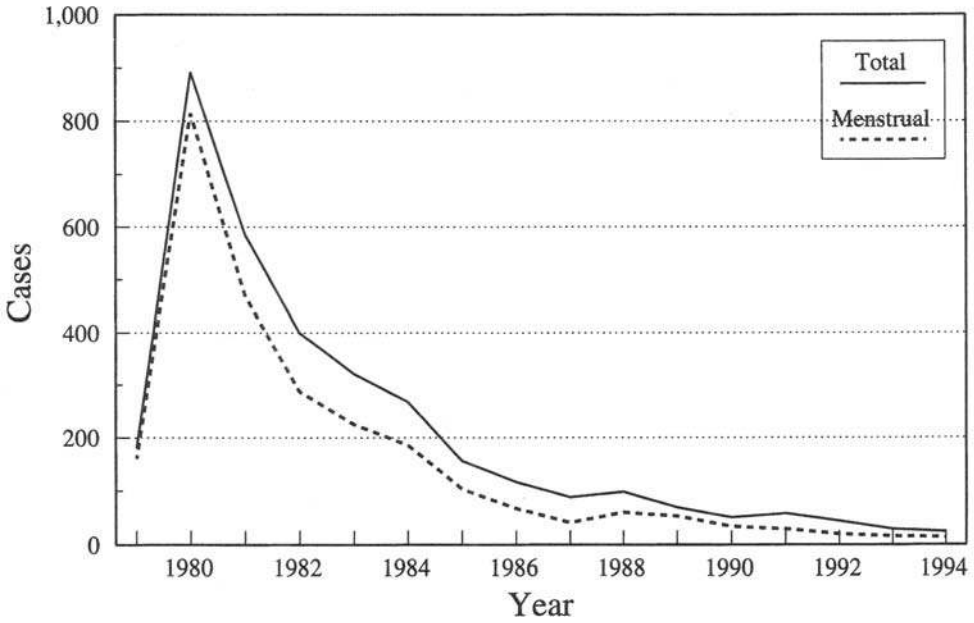

Figure 1. Reported cases of toxic shock syndrome, United States, 1979–1994.

(e.g., Utah and Wisconsin), a different pattern was seen in Minnesota, where no decline in the number of cases was observed in 1981.[60] Because of the documented impact of publicity on reporting of TSS cases and the undoubted fluctuation over time in the likelihood that cases would be diagnosed and/or reported, the results of studies that eliminate or minimize these influences are important in interpreting temporal trends.

While the three published hospital record review studies all suffer from having a relatively small number of cases of TSS to analyze statistically, the results of all three studies are consistent. In the California study, the incidence of TSS in women increased consistently through 1980, fell somewhat in 1981 and 1982, and then increased again in 1983, while the incidence in men remained consistently low (Figure 2). In the Colorado study, the results were similar except that the decrease in 1981 compared with 1980 was sharper (Figure 3). The similarity of the pattern in Colorado is even more apparent if cases meeting only the authors' proposed screening definition for TSS and not the more rigorous collaborative case definition are removed.[61] Similar trends are seen in the study from Cincinnati, although incidence rates cannot be estimated in this study.[20]

Thus, there is convincing evidence that hospitalized cases of TSS in females of menstrual age increased in the late 1970s, irrespective of any changes in the recognition and reporting of the disease. A similar increase was not apparent among men. There is also some evidence that this upward trend in the incidence of TSS through 1980 was reversed in several geographic areas, at least temporarily, in 1981.

5.5. Age

TSS can occur in individuals of all ages and has been documented in a newborn baby and in patients up to 80 years of age. However, data from both passive and active surveillance systems and from the California record review study indicate that younger women are at greater risk of developing TSS than older women. Of cases associated with menstruation reported nationally, almost 60% have been in women 15–24 years of age, compared with only 25% in women 25–34 years of age.[9,10] Cases in women 35–44 years of age are even less common. Furthermore, the highest age-specific incidence rates have been observed consistently in women 15–19 or 15–24 years of age. Thus, in the California record review study, the annual incidence rate was 2.6/100,000 women 15–19 years of age compared with rates of 0.8–1.4/100,000 among women 20–24, 25–29, and 30–34 years of age.[11] Similarly, in Minnesota the annual incidence of menstrual TSS among women 15–24 years of age was 13.7/100,000 compared with rates of 2.3 in those <15 years of age and 6.6 in those ≥ 25 years of age.[56] The age distribution of TSS cases unassociated with menstruation is more uniform, especially if cases in postpartum women are excluded.[30]

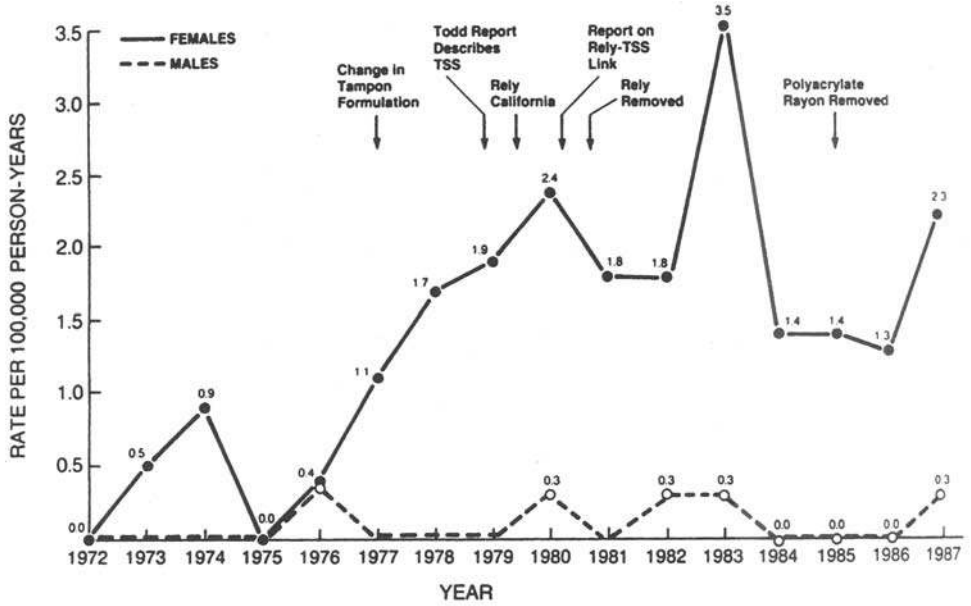

Figure 2. Incidence of hospitalized toxic shock syndrome cases in males (*dashed line*) and females (*solid line*), aged 15–34 years, northern California Kaiser-Permanente Medical Care Program, 1972–1987. Reproduced from Petitti et al.[21] with permission.

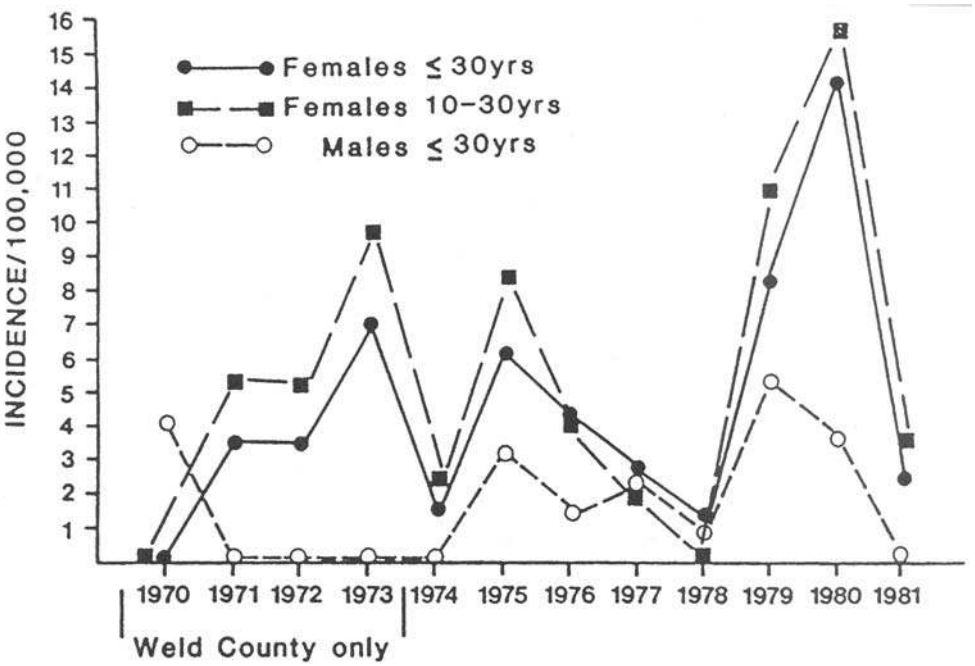

Figure 3. Annual incidence per 100,000 population of toxic shock syndrome in hospitalized patients ≤30 years of age meeting either the strict or the screening case definition in two Colorado counties, 1970–1981. Reproduced from Todd et al.[12] with permission.

5.6. Sex

All available evidence clearly indicates that TSS is much more common among women of menstrual age than among men of the same age. Of US cases reported through passive surveillance, 95% have been in women and 5% in men.[9,10] In the California record review study, the overall incidence of TSS in women 15–34 years of age during the time period 1972–1983 was 15 times that in men of the same age (1.5 vs. 0.1/100,000) person years.[11] This marked difference in incidence rates between men and women undoubtedly relates primarily to the fact that most cases of TSS are associated with menstruation and tampon use. What appears to be an increased risk of TSS during the postpartum interval and the apparent association between TSS and the use of barrier contraception probably contribute further to this pattern.[29,30,62] The incidence of TSS associated with other types of staphylococcal infections (e.g., surgical wound infections, cutaneous and subcutaneous lesions) appears to be similar in men and women.[29,30,59]

5.7. Race

Although it has been apparent since at least 1980 that TSS occurs in individuals of all racial groups,[8] the over-whelming majority (93–97%) of reported cases have been in whites, who make up only 80–85% of the US population.[9,10] Likely explanations for this discrepancy fall into two categories: biases in the diagnosis and reporting of cases on the one hand and true racial differences in either susceptibility to TSS or exposure to risk factors on the other. It has been postulated that increased difficulty in recognizing the rash on dark-skinned individuals, poorer access of minority groups to medical care, and the relative paucity of individuals of races other than white in areas with active TSS research efforts have all contributed to the observed racial distribution of cases. However, data from the California record review study indicate that in the 15–34 age group TSS does indeed disproportionately affect whites.[11] All of the 54 definite cases (most of which are related to menstruation) found in that study were in whites, while only 81% of the population at risk was white ($p < 0.05$; Fisher's exact test, two-tailed).

It has been noted that the racial distribution of patients with nonmenstrual TSS (87% white) more closely resembles the racial distribution of the US population than does the racial distribution of patients with menstrual TSS (98% white).[10,59] Taken together with studies demonstrating that young white women use tampons far more often than do comparably aged women of other racial groups,[63–66] these results suggest that observed race-specific differences in incidence rates are due, at least in part, to different levels of exposure to an important risk factor for developing TSS during menstruation.

5.8. Occupation

There is no evidence to suggest that any given occupational group, including health care providers, is at increased risk of developing TSS.

5.9. Occurrence in Different Settings

As noted below, transmission of strains of *S. aureus* capable of causing TSS has been demonstrated in the hospital setting.[67–69] There is also evidence of spread of these strains and occasional clustering of cases in households and in military installations (CDC, unpublished observations).

5.10. Socioeconomic Factors

It is unclear to what extent the marked racial variation in tampon use, especially among adolescents, reflects socioeconomic rather than racial differences. Other socioeconomic factors have not been noted to play a role in TSS.

5.11. Other Factors

5.11.1. Menstrual TSS. Numerous case–control studies conducted in 1980–1981 examined risk factors for developing TSS during menstruation (Table 2). These studies consistently found that tampon use increased the risk of menstrual TSS (the Oregon study, with its small number of cases, while not finding an association between menstrual TSS and tampon use in general, did find an association with a particular brand of tampon).[5,6,15,16,58,70] Included among these studies are two performed before any information concerning this association had appeared in the medical literature or lay press.[5,6] A study comparing tampon use among women with menstrual TSS in 1983 and 1984 with tampon usage patterns ascertained via a national survey found evidence of a continuing increased risk of menstrual TSS among tampon users.[13] Furthermore, a multistate case–control study of menstrual TSS cases with onset in 1986–1987 documented that this association persisted at that time.[18] No additional case–control studies have been conducted since that time.

Two early case–control studies demonstrated that the risk of menstrual TSS varied with tampon brand and/or style (i.e., absorbency), suggesting that risk was a function of tampon absorbency and/or chemical composition.[15,16] The two more recent studies document clearly that risk of menstrual

TSS is directly correlated with measured in vitro tampon absorbency,[13,18] independent of chemical composition, but that chemical composition is also a factor.[13] It is interesting to note that the correlation with tampon absorbency has persisted, despite the major alterations in chemical composition and marked decreases in the absorbencies of available tampons that have occurred since 1980. A reanalysis of data from earlier studies has suggested that the oxygen content of tampons is a better predictor of the risk of menstrual TSS than either chemical composition or absorbency.[14] In vitro studies examining the effect of various surfactants on TSST-1 production have shown that they can have a dramatic effect on production of this toxin.[71] These results suggest another tampon characteristic (i.e., type of surfactants present) that might influence the risk of menstrual TSS in users of various brands and styles.

The early case–control studies also examined the role of a number of other factors in determining the risk of developing TSS during menstruation. Four of the studies found that women with TSS were less likely to use oral contraceptives than controls, although the differences in individual studies were not statistically significant.[5,6,15,58] One study found that continuous use of tampons during the menstrual period was associated with an increased risk of TSS,[6] while in another study a similar association, present on univariate analysis, did not remain significant in a multivariate analysis.[15] Of four studies looking at the relationship between a history of a recent vaginal infection and the risk of TSS, only one found such an association. Factors found not to be related to the risk of developing menstrual TSS in one of more studies included marital status, income, parity, sexual activity, bathing, frequency of exercise, alcohol use, smoking, history of vaginal herpes infections, and frequency of changing tampons.

5.11.2. Postpartum TSS. Although numerous cases of TSS occurring during the postpartum interval have been reported, the lack of precise information concerning the incidence of TSS in various settings makes it difficult to be certain that the incidence in postpartum women is elevated. Those cases of postpartum TSS not related to infection of a

cesarean section incision or an infection of the breast (i.e., mastitis and breast abscess) have occurred predominantly in association with the use of tampons to control the flow of lochia or the use of barrier contraception (i.e., diaphragms and contraceptive sponges).[30]

5.11.3. Postoperative TSS. TSS has been associated with *S. aureus* surgical wound infections following a wide array of surgical procedures.[68] It has been suggested, however, that patients undergoing nasal surgery are at particularly high risk, presumably due to the frequency of *S. aureus* carriage in the nasopharynx and the difficulty of eradicating such carriage.[22] The common use of "nasal tampons" and other packing material following nasal surgery also may play a role.

5.11.4. Other Nonmenstrual TSS. TSS can result from *S. aureus* infection at any body site. However, many nonmenstrual TSS cases are the result of cutaneous and subcutaneous *S. aureus* infections. Also, cases of TSS associated with *S. aureus* infection of the respiratory tract in the setting of influenza have received substantial attention.[72] Risk factors for the development of such infections and/or associated TSS have not been studied. A relatively small proportion of nonmenstrual, nonpostpartum TSS cases are associated with vaginal *S. aureus* infections. One risk factor that has been identified in such cases is the use of contraceptive sponges.[62] It remains uncertain whether or not diaphragm use is similarly associated with an increased risk of nonmenstrual TSS.

6. Mechanisms and Routes of Transmission

Like all *S. aureus* strains, those capable of causing TSS appear to be transmitted readily by person-to-person spread, both within the hospital and in the community. There is convincing evidence that a nurse transmitted a TSS-associated strain of *S. aureus* to hospitalized burn patients[67] and suggestive evidence that some cases of postoperative TSS are due to nosocomial spread of the causative organism by hospital personnel.[68,69] In addition, vertical transmission from mother to newborn, with the development of TSS in both, has been reported.[73] Outside the hospital setting, transmission between husband and wife has been suggested by the almost simultaneous appearance of TSS in both, as has transmission between mother and daughter pairs (unpublished reports to the CDC). It is assumed, but not proven, that transmission in all these instances was by direct person-to-person spread. Nevertheless, it should be emphasized that in many TSS cases, particularly those associated with a focus of infection in the vagina, it may well be that the disease is due to the introduction and/or multiplication of an endogenous *S. aureus* strain rather than to an exogenous source of infection.

7. Pathogenesis and Immunity

TSS results from an infection with an appropriate strain of *S. aureus* in a susceptible host. Once a nidus of infection is established, onset of symptoms typically occurs 1–3 days later. The best evidence concerning incubation period comes from patients with postoperative TSS due to surgical wound infections. In these patients, the date when the infection became established is usually the day of surgery, and thus can be determined unequivocally. The median incubation period in such patients is 2 days.[68] When TSS is caused by *S. aureus* infection of the vagina during menstruation, onset of symptoms is typically on the third or fourth day of menstruation, although it can be earlier or later.

In most cases of TSS, the toxin TSST-1 is the bacterial product most likely to be responsible for many of the observed signs, symptoms, and abnormalities of laboratory values. There is, however, substantial evidence that one or more other staphylococcal products, particularly enterotoxin B, are capable of causing an indistinguishable illness.[44,46] Furthermore, bacterial products other than TSST-1 that are made more commonly by *S. aureus* strains recovered from patients with TSS than by other strains have been described (see Section 4). For these reasons, it is likely that other staphylococcal products play a role in the pathogenesis of TSS. Furthermore, there is evidence that some of the multisystem derangements frequently observed in patients with TSS are due to the profound hypotension or shock that can occur and only indirectly to any staphylococcal products. For example, renal failure in TSS is probably secondary to hypotension-induced acute tubular necrosis, which in turn is the result of multiple factors, including hypovolemia due to vomiting, diarrhea, increased insensible losses associated with a high fever, and inability to ingest or retain fluids; and "thirdspacing" of fluids. Uptake of "endogenous" endotoxin from gram-negative intestinal flora also has been proposed as playing a role in the pathogenesis of TSS.[74]

The biological properties of TSST-1 have been studied in vitro and in vivo, and attempts have been made to develop an animal model of TSS. In vitro, purified TSST-1 has been shown to stimulate the proliferation of T lymphocytes,[75] to inhibit immunoglobulin synthesis,[76] and to be a potent stimulator of interleukin-1 production by macrophages and monocytes.[77,78] TSST-1 also has been shown to bind to and be internalized by epithelial cells,[79] suggesting that it can be absorbed from focal sites of infection. In vivo, TSST-1 has been shown to be pyrogenic,[40] to induce lymphopenia,[80] to

decrease the clearance of endotoxin,[81] and to increase susceptibility to endotoxin-induced shock.[74] It is now clear that many of the effects of TSST-1 are due to its potent "superantigen" properties, acting through the release of immune cytochines.[82] While initially reported to be an enterotoxin (as evidenced by induction of vomiting in monkeys), preparations of TSST-1 not contaminated with other staphylococcal enterotoxins do not appear to induce vomiting.[83]

Attempts to reproduce TSS in animals have included using mice, rabbits, goats, baboons, chimpanzees, and rhesus monkeys.[55,84–93] In these studies, investigators either have attempted to infect the animals with TSS-associated *S. aureus* strains at one of a variety of sites (previously implanted subcutaneous chambers, vagina, uterus, and muscle) or have injected purified TSST-1 as a bolus or continuous infusion. The animal models that come closest to reproducing the syndrome observed in humans have been those using rabbits. Live TSS-associated *S. aureus* organisms inside a previously implanted subcutaneous chamber and continuous infusion of purified TSST-1 both result in fever, hyperemia of mucous membranes, hypocalcemia, elevated creatinine phosphokinase (CPK) and hepatic enzymes, renal failure, and death in a high proportion of rabbits.[84,88] Also, the pathological changes observed postmortem in these animals are similar to those reported in patients dying of TSS.[94,95]

These rabbit models have been used to study the host factors in susceptibility to TSS suggested as important by clinical and epidemiological data or by in vitro results. It has been found that the age, sex, hormonal status, and strain of rabbits used all have a substantial impact on susceptibility to "rabbit TSS."[85,86] Thus, older rabbits have been reported to be more susceptible than younger rabbits. Similarly, male rabbits appear to be more susceptible than female rabbits, although castration abolishes this difference and estrogens protect male rabbits. Experiments concerning the contribution of endogenous endotoxin (i.e., endotoxin released by gut flora) to the pathogenesis of TSS have yielded conflicting results, although it appears that blocking the effect of endotoxin by giving polymyxin B does not consistently prevent rabbit TSS.[88] Preexisting anti-TSST-1 antibody, however, does appear to protect against TSS in the rabbit,[91] and corticosteroids in high doses also decrease mortality.[88]

Because of the observed association between menstrual TSS and tampon use, many investigators have looked at the effect of tampons and their constituents on the growth of *S. aureus* and the production of TSST-1 in vitro. At the same time, the effect of environmental conditions such as pH, PO_2, PCO_2, and cation concentration on the production of TSST-1 has been investigated. In general, studies have shown that tampons and their individual components inhibit the growth of *S. aureus* in vitro, regardless of the growth medium.[96,97] Although some studies have suggested that *S. aureus* can use various tampon constituents as an energy source, these results have been challenged and their relevance to human disease questioned.[98–100] Also controversial is the effect of tampons on the production of TSST-1 in vitro, with some studies showing that certain tampons and tampon constituents increase TSST-1 production and other studies showing no effect or inhibition of toxin production.[97,99] It has been suggested that the effect of tampons on TSST-1 production (and possibly on the risk of menstrual TSS) is mediated by changes in the availability of magnesium, which is bound by certain tampon components.[101] The various types of surfactants found on tampons also appear to influence the production of TSST-1, at least in vitro.

Growth conditions appear to be important in determining the amount of TSST-1 produced. Thus, an aerobic environment, neutral pH, and low levels of glucose, magnesium, and tryptophan all increase TSST-1 production, although some controversy has arisen about the effect of magnesium concentration on TSST-1 levels.[101–105] It has been shown that in patients with TSS related to focal sites of *S. aureus* infection, growth conditions within the infected focus are well suited to TSST-1 production.[105] Also, while the vagina generally has been considered to be anaerobic, studies have shown that a substantial amount of oxygen is introduced when a tampon is inserted, leading to speculation that the amount of oxygen introduced with a tampon may be an important factor in explaining the increased risk of menstrual TSS among tampon users.[106] A role for proteases of either bacterial or human origin in the pathogenesis of TSS also has been suggested.[105] An earlier theory that the association between menstrual TSS and tampon use was mediated by the demonstrated induction of vaginal ulcerations by tampons[107] has received less attention ever since similar vaginal ulcerations were reported in at least one patient with menstrual TSS who did not use tampons.[94]

8. Patterns of Host Response

8.1. Clinical Features

An illness meeting all the criteria of the established TSS case definition is, by the very nature of the criteria, severe, and the majority of such patients are hospitalized for treatment. Some patients experience the relatively gradual onset of sore throat, fever, fatigue, headache, and myalgias over 24–48 h, followed by vomiting and/or diarrhea, signs of hypotension, and the appearance of the characteristic diffuse "sunburnline" macular skin rash. Other patients appear to

have a much more dramatic onset over the course of several hours, with some reporting that they can remember the exact moment when they suddenly felt overwhelmingly ill.

Because an established set of strict criteria is used to define someone as having or not having TSS, all of the cases so defined are, not surprisingly, alike, regardless of the site of infection with *S. aureus*. There is, however, some variation. The temperature elevation in patients with TSS, while sometimes modest, can be extreme, with temperatures in the range of 104–106°F being fairly common. The evidence of hypotension in an individual case can range from mild orthostatic dizziness to profound shock. The characteristic macular skin rash can be dramatic and obvious, with the patient appearing bright red throughout; it can be subtle and difficult to appreciate, particularly in dark-skinned individuals; or it can be localized. Similarly, the desquamation that occurs during convalescence (usually 5–15 days after the acute illness) can be of subtle flaking and peeling of skin on the face and/or trunk or can involve the loss of full-thickness sheets of skin, particularly on the fingers, hands, and feet. Depending on which systems are affected most prominently in an individual case, the multisystem involvement in TSS can produce rather different clinical pictures. In some patients the involvement of the mucous membranes (e.g., sore throat, conjunctival and oropharyngeal injection) is severe and most prominent, while in other patients the gastrointestinal symptoms (vomiting and/or diarrhea) are predominant. Similarly, myalgias, thrombocytopenia, and involvement of the hepatic and renal systems can range from nil to severe. One study has suggested that the clinical spectrum of disease differs between menstrual and nonmenstrual TSS cases.[45]

Patients who receive aggressive supportive therapy (e.g., fluids), appropriate antimicrobial agents, and drainage of any focal *S. aureus* infection usually respond rapidly and improve over the course of several days. However, patients in whom therapy is either delayed or in whom a focal *S. aureus* infection is not eradicated can have a stormy, life-threatening course. In cases meeting all the established criteria, the case-fatality ratio is 1–3% overall, although it increases with increasing age.[19]

The spectrum of illness of TSS has not been defined adequately due to the lack of a specific diagnostic laboratory test. It is evident that some illnesses not meeting all the criteria of the strict case definition, which was devised for use in epidemiological studies, represent milder forms of TSS. For example, few would question that an individual whose highest recorded temperature was 101.8°F, but who otherwise met all of the established criteria, had TSS. A number of authors have described patients of this kind,[108,109] and some have attempted to fashion simplified and/or less rigorous case definitions for TSS.[110] It is apparent that less rigorous case definitions are likely to be more sensitive but less specific in identifying TSS cases. Ultimately, however, it is not possible, in the absence of a specific diagnostic test, to determine where along a spectrum of increasingly milder and/or more atypical cases illnesses cease to be TSS and start to be something else. Thus, it is unclear whether a tampon-using menstruating woman with *S. aureus* in the vagina (or anyone else) who experiences headache, fatigue, and nausea could represent a very mild form of TSS. Such distinctions are made all the more difficult because of the relative frequency with which completely asymptomatic individuals are colonized with TSST-1-producing *S. aureus* in the nasopharynx, vagina, and probably other sites that are not normally sterile.

8.2. Diagnosis

As noted above, TSS can occur in individuals of any age, sex, and race. However, most recognized cases occur in a limited number of clinical settings. In women of reproductive age, TSS is most commonly seen during the menstrual period and the postpartum interval, although it can occur at other times as well, in association with focal *S. aureus* infections and in users of barrier contraception. TSS during pregnancy, however, is quite uncommon. Although patients undergoing nasal surgery may be at elevated risk, TSS related to a surgical wound infection is a possibility in any postoperative patient, particularly during the first 24–72 h. In many such instances, there will be few or no local signs that the operative site is infected.[68] As noted above, the median interval between surgery and onset of TSS in such cases is 2 days, but the range is 12 h to many weeks. TSS in an infrequent but serious consequence of focal *S. aureus* infections at every conceivable body site, although cutaneous and subcutaneous abscesses and other similar infections appear to predominate. In addition, TSS has been reported to be a life-threatening complication of postinfluenza *S. aureus* infections of the respiratory tract.[111,112]

The differential diagnosis for a patient suspected of having TSS depends, in part, on which features of the illness are most prominent. For example, patients in whom sore throat and fever predominate early are frequently suspected initially of having streptococcal or viral pharyngitis. In cases in which diarrhea and vomiting are more prominent, viral gastroenteritis is often considered. When the rash becomes apparent, scarlet fever, streptococcal TSS, and drug reactions are often suspected.

The differential diagnosis also can be influenced by the patient's age and sex and the clinical setting in which the illness occurs. For example, cases in infants and very young children must be distinguished from Kawasaki

Table 3. Differential Diagnosis in Patients with Suspected TSS

Kawasaki syndrome
Scarlet fever
Meningococcemia
Leptospirosis
Measles (especially "atypical")
Rocky Mountain spotted fever
Viral gastroenteritis
Viral syndromes with exanthems
Appendicitis
Pelvic inflammatory disease
Tubo-ovarian abscess
Staphylococcal scalded skin syndrome
Drug reactions/Stevens—Johnson syndrome

syndrome and staphylococcal scalded skin syndrome. Similarly, in postpartum or postabortion women, other causes of fever and hypotension must be considered, such as endometritis and septic abortion. In individuals with appropriate exposure histories, leptospirosis, measles, and Rocky Mountain spotted fever should be included in the differential diagnosis. In summary, TSS can be confused fairly readily with a wide range of other conditions (Table 3).

9. Control and Prevention

9.1. General Concepts

9.1.1. Menstrual TSS. Most strategies for decreasing the incidence of TSS have focused on menstrual TSS and its relationship to tampon use. In light of the demonstrated association between tampon use and risk of developing menstrual TSS, women were advised in 1980 that they could minimize their risk of developing menstrual TSS, women were advised in 1980 that they could minimize their risk of developing menstrual TSS by not using tampons. In response, many women stopped using tampons, at least temporarily. The proportion of menstruating women who used tampons fell from approximately 70% in 1980 to less than 50% in 1981, but has rebounded to approximately 60–65% since that time.

In response to epidemiological and in vitro laboratory evidence concerning the possible roles of tampon absorbency and chemical composition in determining risk of menstrual TSS, most tampon manufacturers have dramatically altered both the absorbency and chemical composition of their products. After increasing markedly in the late 1970s, the measured in vitro absorbency of tampons has dropped sharply since 1979–1980, and one component, polyacrylate, has been eliminated from tampon formulations. In addition, one brand of tampons found to be associated with a high risk of menstrual TSS was withdrawn from the market altogether in 1980. All tampons sold in the United States 2005 were made of cotton, rayon, or a blend of cotton and rayon.

All tampons now carry a label explaining the association between tampon use and menstrual TSS and describing the signs and symptoms of the illness. Tampon packages also carry a statement that women should use the lowest absorbency tampon consistent with their needs. Uniform absorbency labeling of tampons was required by the Food and Drug Administration beginning in 1989.

Although frequent changing of tampons has been recommended as a way of decreasing the risk of menstrual TSS, there is no evidence to suggest that changing tampons more often reduces risk. Evidence from one study suggests that alternating tampons and napkins during a menstrual cycle may decrease the risk of TSS.[6]

9.1.2. Postpartum TSS. Because women may be at increased risk of TSS during the postpartum period, they should avoid the use of tampons and barrier contraception during that interval.

9.1.3. Hospital-Acquired TSS. Other than those measures designed to minimize nosocomial infections in general (e.g., good hand-washing practices) and those recommended specifically for patients with other types of staphylococcal infections, there are no proven methods for decreasing the risk of TSS associated with infected surgical wounds and other nosocomial *S. aureus* infections.

9.2. Antibiotic and Chemotherapeutic Approaches to Prophylaxis

Appropriate antimicrobial therapy of an initial episode of menstrual TSS, combined with discontinuing tampon use, has been shown to reduce the risk of recurrent episodes during subsequent menstrual periods.[5] The value of follow-up cultures and prophylactic antimicrobial agents in women with a history of menstrual TSS is unproven, although such measures may be justified in women who have had recurrent episodes of TSS. Because carriage of *S. aureus* at various body sites is so common and cases of TSS are relatively rare, there is no role for obtaining cultures from or giving chemoprophylaxis to individuals without a prior history of TSS.

9.3. Immunization

Although some consideration was given to attempting to develop a toxoid vaccine from TSST-1 soon after its discovery, no concrete steps in this direction have been taken. Given the high proportion of the population with naturally occurring anti-TSST-1 antibodies and the relative rarity of

TSS, it would be prohibitively expensive and impractical to demonstrate that such a vaccine yielded clinical protection.

10. Unresolved Problems

Unresolved problems in our understanding of TSS relate primarily to its pathophysiology. While a clear link between the use and risk of menstrual TSS has been established, the specific characteristics of tampons responsible for this increased risk are unknown. The relative importance of absorbency, chemical composition, oxygen content, and perhaps other tampon characteristics, such as the surfactants used in their manufacture, in determining risk is uncertain. Similarly, while a direct correlation between measured tampon absorbency and risk of menstrual TSS has been demonstrated, it remains unclear whether or not users of the lowest absorbency tampons are at greater risk than nontampon users. At the same time, the role of tampon chemical composition in determining risk is ill-defined. As a result of all these uncertainties, it is unknown whether or not the "perfect tampon" (i.e., one that offers menstrual protection and has no associated increased risk of menstrual TSS) currently exists or can be developed.

CHAPTER 40

Tuberculosis

Diana S. Pope, Richard E. Chaisson, and George W. Comstock

1. Introduction

Tuberculosis is a contagious disease spread through the air in tiny droplet nuclei. Propelled into the air by the cough, sneeze, or speech of a person sick with pulmonary tuberculosis, *Mycobacterium tuberculosis* bacilli can stay suspended for prolonged periods of time, ready to be inhaled by others sharing the same airspace. *M. tuberculosis* usually results in latent infection controlled by cellular immunity and may later progress to active disease. Though primarily a pulmonary disease, tuberculosis can affect many organs, and continues to be a major cause of illness, disability, and premature death throughout the world. Tuberculosis has been curable for more than 50 years; a standard drug regimen of specific antibiotics for a minimum of 6 months is required.

In 1997 the World Health Organization carried out the first worldwide survey of the global burden of tuberculosis and estimated that on average, one person is infected with tuberculosis every second of every day.[1] In fact, one-third of the world's population, approximately 2 billion people, is infected with TB. Those that are infected are often concentrated in populations that suffer from crowding, poor nutrition, and all the other manifestations of poverty. Even so, most of these people will probably never know they are infected and will never develop active TB disease.

The epidemiology of tuberculosis has changed dramatically over the last decade in some parts of the world; human immunodeficiency virus (HIV) infection has struck a punishing blow to even well-functioning TB control programs. The impact is so massive that, despite improvements in case-finding and treatment completion, tuberculosis increased at an annual rate of 1% worldwide, until it peaked and began to stabilize in 2005.[2] The widespread development and subsequent transmission of multidrug-resistant tuberculosis in regions suffering from collapsing public health infrastructure has added yet another dimension to the difficulties in controlling this ancient human disease.

In 1998, the complete genome of *M. tuberculosis* was fully sequenced. The genome comprises 4,411,529 base pairs and contains around 4,000 genes. *M. tuberculosis* differs radically from other bacteria in that a very large portion of its coding capacity is devoted to the production of enzymes involved in lipogenesis and lipolysis and to two new families of glycine-rich proteins.[3] The sequencing of the genome has resulted in numerous advances in TB epidemiology, pathogenesis, diagnostics, drug development, and vaccines.

2. Historical Background

Descriptions of tuberculosis can be recognized in many older medical writings, usually as *phthisis* or *consumption*, described as a chronic wasting illness associated with *ulcerations* of the lungs; as *galloping consumption*, the pneumonic form of the disease; or as *scrofula*, an involvement of the cervical lymph nodes. That the various forms of tuberculosis had a common and infectious etiology was first established by Villemin in 1865. He showed that inoculation of material from the various forms of tuberculosis lesions caused a similar disease in rabbits, as did the inoculation of sputum from patients with pulmonary lesions. Klebs also demonstrated the transmissibility of tuberculosis from man to animals in 1877, and even produced culture media for the growth of tubercle bacilli.[4]

Five years later, in 1882, Robert Koch announced his discovery of the tubercle bacillus and a means of staining it for microscopic examination. Only then did it become feasible to make a definitive diagnosis of tuberculosis and to identify disseminators of the organism. Koch made another fundamental contribution to the epidemiological armamentarium by producing tuberculin in 1890. Although his claim for the therapeutic use of tuberculin was discredited, it was soon recognized that an infected person could be identified by the local reaction that followed the injection of a small amount of tuberculin into the skin. The third major diagnostic procedure resulted from the discovery of X-rays by Roentgen in 1895. Radiographs of the chest made it possible to demonstrate pulmonary disease before it could be recognized clinically and sometimes before it became communicable.

Refinements of these fundamental diagnostic procedures occurred for the most part during the 1940s and 1950s and added greatly to their usefulness. Development of specific culture media made it possible to detect much smaller numbers of tubercle bacilli than could be demonstrated by microscopic examination of stained specimens; furthermore, cultures were less expensive and more widely applicable than guinea pig inoculations, which were originally used to confirm microscopic examinations. Photofluorography brought chest radiography to the general population in mass surveys designed to detect early asymptomatic cases of pulmonary tuberculosis. Improvements in the standardization, administration, and interpretation of the tuberculin test made it possible to identify, albeit with some misclassification, people who had been infected with *M. tuberculosis*.

In recent years, new molecular techniques, such as nucleic amplification techniques (e.g., polymerase chain reaction), now make it possible to detect even smaller numbers of tubercle bacilli in biological specimens in as short a time as several hours, to rapidly identify organisms in culture.[5] Furthermore, DNA fingerprinting techniques, such as restriction fragment length polymorphism analysis and spoligotyping, allow the transmission of tuberculosis to be elucidated, adding significantly to epidemiologic research and public health practice.

From the 1860s to the 1940s, tuberculosis killed more people each year in the United States than any other contagious disease—one out of every seven deaths was from TB. In 1861 Oliver Wendell Holmes referred to consumption as the *white plague*. The history of tuberculosis control, in Europe and the United States, is closely entwined with the sanatorium movement, which espoused healthful living, with particular emphasis on rest, good food, and fresh air. In addition, the isolation of patients in sanatoria during their "treatment" undoubtedly reduced the risk of transmission of their disease to others. Historian JoAnne Brown found that following the civil war, military metaphors proliferated, many of them harkening back to the days of knighthood, an era from which civil war soldiers took inspiration, espousing chivalric deeds. It was in this social environment of a sanctified "battle" against germs that the Lorraine cross was selected as the symbol of the efforts to combat lung diseases, including tuberculosis.[6]

Although the basic precepts of the sanatorium movement can be traced back to the temples of Asclepius, (or Aesculapius, as he was known to the Romans), they did not receive wide acceptance as treatment for tuberculosis until the successful establishment of sanatoria by Brehmer in the mountains of Silesia in 1854 and by Trudeau in the Adirondack mountains of New York in 1882. Sanatorium treatment became the major tuberculosis control activity for decades, diminishing in importance only with the introduction of effective antibiotics, notably streptomycin in 1946, para-amino salicylate (PAS) in 1948, and isoniazid in 1952. Successful treatment on an outpatient basis then became possible, and the days of the sanatoria came to an end over the ensuing decade. The demonstration in India in the early 1960s that ambulatory therapy was safe and effective for both patients and their family contacts made hospitalization or institutionalization of TB patients unnecessary and solidified the emphasis on outpatient treatment. Further advances in the treatment of tuberculosis and discovery of other antimycobacterial drugs have led to shortening of therapy to 6 months and intermittent administration of medications.

Specific preventive measures began with the development of an attenuated strain of *Mycobacterium bovis*, a member of the MTB complex, by Calmette and Guérin between 1908 and 1919. The vaccine prepared from this strain came to be called bacille Calmette–Guérin, or BCG. Accepted at first with reluctance, subsequent clinical trials demonstrated substantial protection from TB and death, and use of the vaccine increased over several decades. BCG is a live attenuated vaccine, and no seed lot of the original strain has been preserved. As discussed below, multiple progeny of the original BCG are now in use globally, and vaccination with one of the many substrains has become a mainstay of childhood immunization programs throughout the world.

During the 1950s, large-scale controlled trials demonstrated that people infected with tubercle bacilli could be protected from the subsequent development of disease by the administration of isoniazid. Subsequent studies have demonstrated the risks and benefits of isoniazid (and rifamycin) for treatment of latent TB infection, but use of preventive therapy remains curiously limited in most of the world.

Tuberculosis mortality began to decline in developed countries prior to the present century, long before

tuberculosis control measures could have had any general effect. Dubos and Dubos[4] pointed out that where the decline could be documented by death records, sanitary and social reform movements in the early nineteenth century brought about many improvements in living conditions that would tend to operate against the tubercle bacillus. At the same time, in parts of the developing world, through colonization and the changing of political boundaries, tuberculosis was being introduced to naïve populations with devastating effects. More specific tuberculosis control measures, such as the use of drugs, played a major role in maintaining the decline throughout most of the world, especially during the later decades of the twentieth century.

Following the introduction of effective drug regimens, the public health and medical communities believed that tuberculosis was a problem of the past and interest waned. Tuberculosis control and research budgets began to be cut, and preventive measures were curtailed. Meanwhile, conditions favoring tuberculosis did not diminish. The divide between the rich and poor continued to become more extreme; refugee populations (including those internally displaced) are in the tens of millions; poverty and all its accompanying attributes of crowded living conditions, poor nutrition, and diminished access to appropriate health care continue to provide conditions ideal for the spread of this infection.

In the early 1980s, when the human immunodeficiency virus (HIV) was being recognized, tuberculosis control efforts in the United States were at an all-time low. It became apparent early on that HIV drastically reduced resistance to tuberculosis. At the beginning of the 1990s, multidrug-resistant tuberculosis became a major problem, particularly in New York City and surrounding areas, fueled by collapsing health systems and HIV infection. The concern engendered by the emergence of strains of tuberculosis that were potentially incurable resulted in an increase in interest and funding.

The World Health Organization (WHO) has played a leadership role in bringing tuberculosis control back to the forefront as a global priority. The Bill and Melinda Gates Foundation has identified tuberculosis as an important disease to control and as a result has funded unprecedented research on improved diagnostics, drugs, vaccines, and public health strategies. The United States has set an ambitious goal of reducing TB incidence to less than 1 per million by 2010,[7] and the Group of Eight (G8) leading industrial economies has set the audacious goal of reducing TB prevalence and mortality to half the 1990 levels by 2015. The United States represents only one-half of 1% of all the tuberculosis in the world, so the battle will not be won or lost within its borders. Whether tuberculosis will be eliminated or not is open to question.

3. Methodology

3.1. Sources of Mortality Data

Worldwide tuberculosis deaths and death rates are tabulated in the *World Health Statistics Annual*, published by the WHO in Geneva, Switzerland. Deaths and death rates specific to the United States and its territories can be found in various national vital statistics publications, such as *Vital Statistics of the United States*, published annually by the National Center for Health Statistics, Centers for Disease Control and Prevention (CDC), US Department of Health and Human Services. Annual reports on tuberculosis are also published by the Division of Tuberculosis Elimination, CDC.[8] Useful compendia of older statistics are also available.[9,10]

Although mortality rates have been useful historically as indicators of tuberculosis trends and of regions where tuberculosis cases are concentrated, today, with the advent of effective chemotherapy, mortality rates are often better indices of the lack of access to good medical regimens or lack of adherence to them. Even this use may be jeopardized by the estimate that tuberculosis deaths are markedly underreported in much of the world.[11,12]

Autopsy studies may reveal tuberculosis deaths that would not have been captured by routine surveillance strategies. No longer done routinely, autopsy studies carried out in general or specific populations often reveal evidence of previously undetected active tuberculosis.[13,14]

3.2. Sources of Morbidity Data

Tuberculosis cases and case rates are tabulated and summarized in the publications from the WHO and CDC mentioned in Section 3.1. In addition, the *Morbidity and Mortality Weekly Report* from the CDC and monthly reports from state health departments give up-to-date accounts of reported domestic cases in the United States. However, in 2006 tuberculosis was no longer reported in MMWR, presumably because there were so few cases. The accuracy of TB case-finding and reporting is highly variable in developing countries.[15]

A distinction should be made between reporting TB cases and suspects to a health department and the counting of TB cases for the purposes of determining incidence of disease. Tuberculosis disease can be defined clinically and/or through evidence obtained through laboratory evaluation(s) of clinical specimens. Without laboratory evidence of *M. tuberculosis* complex or demonstration of acid-fast bacilli (AFB) in a clinical specimen, clinical case definitions require three criteria to be counted: evidence of TB infection based

on a positive tuberculin skin test result; signs and symptoms compatible with current TB disease or clinical evidence of current disease; and current treatment with two or more anti-TB medications.[16]

3.3. Surveys

Surveys for tuberculosis have been conducted by means of physical examinations, bacteriological examinations of sputum, chest photofluorography, and tuberculin testing. In 1917, an extensive antituberculosis campaign was carried out in Framingham, Massachusetts, in the course of which approximately 11,000 people, two-thirds of the population, were given physical examinations for tuberculosis.[17] The findings of this survey resulted in the estimate that there were nine prevalent active cases for every annual tuberculosis death, a ratio used for the next three decades in the United States to estimate the size of the tuberculosis problem.

Sputum surveys are limited as a general rule to people with abnormal findings on chest X-ray surveys either to identify cases that are most meaningful from the public health point of view or as a means of surveillance for drug-resistant organisms. Occasionally, in areas where mass radiography is impractical, sputum surveys of general populations have been done to estimate the prevalence of tuberculosis or to detect tuberculosis cases among people with chronic cough.

With the demonstration in Brazil by de Abreu and de Paula[18] in 1936 of the practicability of mass photofluorography, it became feasible to examine the lungs of large numbers of apparently normal people for tuberculosis. In the decade following World War II, millions of people were examined in mass chest X-ray surveys. While it seems reasonable to believe that detection of unrecognized cases of tuberculosis was beneficial, there is little evidence to substantiate this belief. In Wales, an intensive tuberculosis case-finding and treatment program was followed by a decreased risk of new infections among children,[19] and in Alaska, an intensive case-finding and treatment program was followed by a marked decrease in childhood infections.[20]

Use of the tuberculin skin test can contribute a great deal to epidemiological knowledge. The applications of tuberculin testing to the delineation of the risks of having been infected with tubercle bacilli by time, place, and person are epitomized by the work of Palmer and Edwards and their colleagues.[9,21–26] By careful attention to the selection of study populations, to the techniques of administering and reading tuberculin tests, and to the interpretation of frequency distributions of reaction sizes, it has been possible to learn a great deal about the prevalence of infected people under varied circumstances and the implications of these findings for temporal, geographic, and personal differences in the risk of becoming infected.

3.4. Laboratory Diagnosis

3.4.1. Isolation and Identification of the Organism. Tubercle bacilli are commonly looked for in sputum and other specimens by microscopic examination. Preparations stained by the Ziehl–Neelson acid-fast technique allow for the identification of the rod-shaped 1–4 μm long fuchsin-stained mycobacteria. Microscopic examination of stained specimens is relatively quick and inexpensive, but its sensitivity is low. It has been estimated that at least 5,000–10,000 bacilli/ml are needed to make their recognition by microscopy reasonably certain.[27] This is an important examination however; those patients with enough acid-fast bacilli (AFB) organisms to be visualized with a microscope, so called smear positive, represent patients who are the most infectious. With proper laboratory techniques in areas where tuberculosis is common, specificity is fairly high, since acid-fast bacilli seen on microscopy are usually tubercle bacilli; nontuberculous mycobacteria, however, have a similar appearance and can occur as pathogens, as normal inhabitants in oral or genitourinary secretions, or even in water used to wash the slides. However, in areas of high TB prevalence, the positive predictive value of AFB staining is quite high.

Culturing *M. tuberculosis* can detect as many as 30–50% more cases of active tuberculosis, making it much more sensitive than microscopic examination. The ability to visualize the AFB colonies growing on egg-based (Lowenstein–Jensen) and agar-based (Middlebrook agar) media also enhances the specificity. However, with a generation time of nearly 24 h, tubercle bacilli grow slowly, usually requiring 3–8 weeks to form identifiable colonies. Presumptive identification of the various mycobacteria is based on growth rate, colony characteristics, and pigment formation.[28] Faster culture systems that detect mycobacterial growth by sensing radioactive carbon liberation (BACTEC)[29] or oxygen consumption can identify growth in 1–2 weeks. The Mycobacteria Growth Indicator Tube (MGIT) system, a non-radiometric method, cultures specimens in an enriched broth contained in a glass tube. The tube also houses an oxygen sensor embedded in silicone at the bottom of the tube. As the *M. tuberculosis* consumes the oxygen, depleting it within the tube, the sensor becomes fluorescent, which can be easily observed with the use of an ultraviolet lamp.[27,30]

The use of nucleic acid probes or the ρ-nitro-α-acetylamino-β-hydroxypropiophenone (NAP) test can rapidly distinguish *M. tuberculosis* complex from nontuberculous

mycobacteria with considerable accuracy.[5] Nucleic acid amplification techniques have been approved for diagnosing TB in many countries. Both reverse transcriptase-polymerase chain reaction (RT-PCR) techniques and transcription-mediated amplification (TMA) assays can detect *M. tuberculosis* in sputum and other specimens within several hours. Despite the intuitive appeal of these molecularly based, rapid diagnostic assays, their use has been hampered by limited sensitivity and less-than-desirable specificity. Inhibitors present in sputum impede DNA amplification, reducing sensitivity to 85–90% in AFB smear-positive, culture-positive specimens and to only 50–70% in smear-negative, culture-positive specimens.

3.4.2. Serological and Immunologic Diagnostic Methods. The most widely used and thoroughly validated immunologic test for *M. tuberculosis* infection for epidemiological and clinical purposes is the tuberculin skin test. The standard tuberculin test is administered by the Mantoux technique, whereby 0.1 ml of a purified derivative of tuberculin is injected just under the skin of the forearm by needle and syringe. The definition of a positive reaction is best derived from a frequency distribution of reaction sizes in the population under study.[31–33] The optimal dividing line between positive and negative will vary with the proportion of people in the population who have been infected with tubercle bacilli, the frequency of cross-reactions caused by infections with BCG or nontuberculous mycobacteria, and technical factors related to administration and reading of the test.

Some account of these factors has been taken in the several definitions of a positive tuberculin reactor for use in the United States. If the likelihood of tuberculous infection is increased, as it is among people with abnormal chest radiographs or with a history of recent exposure to an infectious case, or in immunocompromised patients (e.g., HIV infection), reactions of 5 mm or more in diameter to 5 tuberculin units of PPD are considered positive and indicate the presence of tuberculous infection. In individuals from settings with an increased risk of TB infection or with medical conditions increasing the probability of developing active TB (e.g., diabetes, renal failure), 10 mm is the cut point. In people at low risk of tuberculosis infection, 15 mm of induration is the recommended cut point.[34] The higher cut point reduces sensitivity but improves specificity.

Although the accuracy of the tuberculin test in detecting past or present infection with tubercle bacilli compares favorably with that of many medical screening tests, there are important sources of error. Errors in dosage, depth of injection, and measurement of reactions can result in misclassification. False-negative reactions may occur up to 8 weeks after infection, in seriously ill patients, during and shortly after viral infections and vaccinations (notably measles), and with natural and induced immunosuppression (e.g., Hodgkin's disease, HIV infection, corticosteroid therapy). Much more common, however, are false-positive reactions caused by infections with nontuberculous mycobacteria or vaccination with BCG.

Identifying recently infected people by means of repeated tuberculin tests of initially negative reactors is simple in theory but difficult in practice. Even with fastidious technique, the results of two tests can vary by 6 mm or more.[35] Consequently, only people whose reactions change from negative to positive and increase by at least 10 mm are considered to have had a true change in tuberculin sensitivity that may have been caused by a recent infection.[36] A further complication in the detection of newly infected people results from the "booster effect," analogous to the anamnestic response in serology. Many people, especially those over 50 years of age, may have had a gradual decline in tuberculin sensitivity to the point where an initial test causes no detectable induration. In some of these previously reactive people, the stimulus of the initial test causes a "boost" of their sensitivity back to its original level.[37] Boosting occurs within 1 week and appears to last for up to 2 years. If these people are given a second test 6 or 12 months later, their positive reactions at that time may have resulted from either the booster effect or a new infection.

To minimize the possibility of falsely attributing a boosted reaction to a new infection, people who are to be tested periodically and who have a low risk of becoming infected (i.e., those who are not household contacts) should have a second test given a week after the initial test if that initial test was negative. People still negative to the second test should then be included in the periodic testing program, with reasonable assurance that any subsequent change to a positive reaction (with an increase of at least 10 mm) will have resulted from a recent infection. People who are positive to the second test of the initial series should be classified as initially positive reactors.[38]

A variety of serological tests for the diagnosis of tuberculosis have been evaluated but have been of limited value due to poor predictive values. Assays that detect cellular immune responses to *M. tuberculosis* infection rather than humoral responses hold considerable promise. There are currently two commercial interferon-gamma (IFN-γ) assays: QuantiFERON®-TB Gold assay[39,40] and T SPOT-TB[41,42] test. Both tests measure the production of IFN-γ by CD4 T-cells in response to specific *M. tuberculosis* antigens. An advantage of both tests is that unlike the TST, they react to only a few species of nontuberculous mycobacteria. This makes it possible to differentiate people infected with *M. tuberculosis*, from those with a history of BCG

vaccination, for example. Like the TST, these tests cannot differentiate between latent infection and active TB disease. A prospective study, completed in Italy in 2005, compared the results of QuantiFERON®-TB Gold assay and the T SPOT-TB test in 393 people suspected of having active or latent TB, 381 of them with known positive TB skins tests. Results of the blood tests were similar to previous studies in the level of agreement with the skin test, but determined that the rates of indeterminate and positive results from each assay differed significantly. The study incidentally discovered that both assays resulted in more indeterminate test results in immunosuppressed patients.[43] There is a reasonably good correlation between the results from these assays and the TB skin test, although they may be measuring responses of different components of cell-mediated immunity, with the major discrepancies in results related to prior BCG vaccination.[44] More, well-designed prospective evaluations of these tests will be necessary to determine their usefulness in identifying individuals with TB infection.

4. Biological Characteristics of the Organism

There are currently 82 recognized species of mycobacteria; most of them ubiquitous in the environment and not pathogenic to humans. *M. tuberculosis* complex includes *M. bovis* and *M. africanum*. Mycobacteria other than *M. leprae* and *M. tuberculosis* complex are referred to as nontuberculous mycobacteria (NTM).

M. tuberculosis is a small, slender (1–4 μm long by 0.3–0.6 μm in diameter), and slightly curved, rod-shaped bacillus that reproduces slowly, approximately once every 24 h. An aerobe, the bacteria are highly adapted to survive within the inhospitable environment of a human alveolar macrophage—inside the very cells designed to attack foreign elements that enter the tiny air sacs of the human lung. Using sophisticated mechanisms to utilize the host's iron and oxygen to survive, *M. tuberculosis* is able to persist for years, frequently for the lifetime of the host.[45]

Tubercle bacilli are particularly resistant to drying, a characteristic attributed to a waxy, lipid-rich cell wall. The high lipid content makes the bacilli resistant to dyes routinely used to stain organisms in laboratories. However once stained, the mycobacteria resist decolorization with acidified organic solvents and are there therefore called *acid-fast bacilli* (AFB), a name synonymous with mycobacteria.

The bacilli are also resistant to most ordinary germicides, particularly in the presence of organic material such as sputum. They are susceptible to moist heat, being killed in approximately 30 min by exposure to temperatures of 60°C and in less than a minute when greater than 70°C.

Laboratory studies have demonstrated that ultraviolet light can disrupt the DNA of *M. tuberculosis*, killing the bacteria. Sunlight and artificial ultraviolet light both appear to be effective in killing these air-borne pathogens.[46] Studies are ongoing to determine effective and safe methods to take advantage of the organism's vulnerability to exposure to these wavelengths.[47,48]

5. Descriptive Epidemiology

The incidence and prevalence of tuberculosis infection and disease vary throughout the nations of the world. Risks for acquisition of TB infection and development of disease can be classified into two major categories: extrinsic and intrinsic. Extrinsic risks include environmental and/or social factors that increase the degree of exposure to TB. Intrinsic risks are factors determined by each individual's genetic makeup, nutritional status, and specific health status. Many extrinsic risks vary by community. Intrinsic risks are constant across populations.

Tuberculosis differs from most other bacterial diseases in a very important respect, namely that the immune response to the primary infection is often not sufficient to rid the body of the organism. As a consequence, an unknown but significant proportion of tuberculin reactors continue to harbor living organisms and at risk of reactivation for the rest of their lives. In epidemiological terms, this means that the incubation period of tuberculosis is highly variable, ranging from a few weeks to a lifetime. Those who pass through the highest-risk period shortly after infection still have a subsequent lifetime risk that may actually exceed the initial risk because of the cumulative effect of a low risk operating over many years.

In thinking epidemiologically about the development of tuberculosis in populations, it is important to look at each of the two major stages of its pathogenesis—the acquisition of infection and the subsequent development of significant disease. While all infectious diseases must go through these two stages, their separation is particularly important in tuberculosis because the known risk factors for infection are so different from the risk factors for the development of disease after infection. Despite the voluminous literature on tuberculosis, very little of the work has been done in such a way that these two risks can be disentangled.

5.1. Prevalence and Incidence

5.1.1. Infection. Information on the prevalence or incidence of tuberculous infections is rarely available on a community-wide basis. Estimating the prevalence of infection can be particularly difficult because the tuberculin skin

test cannot differentiate between the positive reactions that may occur in response to infection with *M. tuberculosis*, nontuberculous mycobacteria, and BCG vaccination. The frequency of cross-reactions from nontuberculous mycobacterial infections varies markedly by geography, being almost nonexistent in the Arctic and common in some tropical and subtropical areas. However, PPD-S, the most widely used tuberculin, elicits larger reactions in individuals with *M. tuberculosis* infection than in those who have been sensitized by BCG or nontuberculous mycobacteria. Larger reactions (>15 mm) are most likely to be due to infection with tubercle bacilli than other mycobacteria.

The longer one lives, the greater one's risk of being exposed to tuberculosis. As a consequence, the prevalence of tuberculous infections rises with age, tending to level off at about 40–50 years. The incidence of tuberculosis infection is usually estimated from the change in prevalence of tuberculin reactors by age rather than from repeated testing of the same individuals.[49,50] This strategy minimizes errors in classification caused by technical variations in testing and reading and also those caused by the effects on the second test of the stimulus from the first test, the so-called booster effect (see Section 3.4.2).[51] The annual risk of infection (ARI) is calculated from tuberculin skin test surveys of representative samples of non-BCG-vaccinated children. For example, if a sample of unvaccinated 6-year-olds had a prevalence of TB infection of 6%, the annual risk of infection would be 1%.[52]

The incidence of new TB infections appears to have been decreasing globally over the past half century, though there is enormous variation by region.[20] Currently, The ARI is highest in sub-Saharan Africa (1.5–3.5%) and Asia (1.0–2.0%). In comparison, the ARI in the Netherlands in 1985 was estimated at 0.012%.

ARI can be used to estimate the incidence of sputum smear-positive pulmonary TB. Based on data from countries where both ARI and the rates of smear positivity were known, for every 1% ARI, there are approximately 49 cases (95% confidence interval 39–59) of smear-positive TB per 100,000 population.[52] This estimation, however, is based on data from developed countries in an era of TB decline and may not be representative of TB in developing countries at present, especially those countries with large HIV epidemics.

Another useful function of large-scale TB skin test surveys is to determine the relative differences in risks of infection between different population groups. Studies carried out in the last decade in Canada, Nepal, and Taiwan have all demonstrated that aboriginal populations continue to suffer disproportionate risk of infection with tuberculosis.[51,53,54] In India, data from ARI surveys carried out between 2000 and 2002 in a variety of locations throughout the country showed great variability in the risks of infection between rural and urban populations ranging from 1.2 to 3.8%.[55]

On the basis of a variety of data, including tuberculin surveys, back calculation from reported case rates, and other information, the estimated global prevalence of TB infection is 2 billion, or one-third of the world's population. This widely quoted figure is clearly only an estimate, but it is probably not too far off the mark, though certainly imprecise.

5.1.2. Disease. The frequency of tuberculous disease depends first on the prevalence of infection and second on the ability of infected people to contain that infection. The prevalence of a disease is a function of its incidence and average duration.

In 2003, there are believed to be 15.4 million prevalent TB cases globally (245/100,000), of which 6.9 million (109/100,000) were smear positive. An estimated 1.7 million people (28/100,000) died from TB in 2003, including those co-infected with HIV (229,000).[56] In 2004, an estimated 264,000 TB patients co-infected with HIV died.[57] The risk of tuberculosis disease varies widely throughout the world, the result of wide differences in the risk of infection and co-morbidities contributing to individual risk of disease if infected.

5.2. Epidemic Behavior and Contagiousness

Tuberculosis can and sometimes does occur in sharply localized outbreaks. In nearly all such instances, these involve the exposure of previously uninfected people to an infectious individual in crowded quarters. Perhaps the most remarkable aspect of these outbreaks is their relative rarity, given the frequency with which uninfected individuals are exposed to infectious cases in homeless shelters, schoolrooms, and factories.[58–62] A possible explanation is that some tuberculous patients are more effective spreaders than others. Another factor that may play a role is that tuberculosis is usually not highly communicable.[63] A study published in 2000 that reviewed the outcomes of contact investigations reported to the CDC from July 1996 through June 1997 for 1,080 pulmonary sputum-smear-positive TB patients (the most infectious TB patients), identified a total of 6,225 close contacts, 43% in the household. Thirty-six percent of all the contacts were TB skin test positive, and only 21% of children younger than 6 years of age were positive.[64] In contrast, secondary attack rates among 5- to 9-year-old household associates of cases of measles and mumps have been reported to be 81 and 86%. Because the communicability of measles or mumps is measured in days, while that of tuberculosis is measured in weeks or months, the infectiousness of tuberculosis per day of exposure must *on average* be very low indeed.

There is good evidence that the dosage of infection is related to the risk of developing tuberculosis.[65,66] Both among nurses in the Prophit Survey in England and white and Indian children in western Canada, positive tuberculin reactors who had been most heavily exposed were more likely to develop tuberculosis than tuberculin reactors with less exposure.[67,68]

The infectiousness of tuberculosis patients appears to be rapidly reduced by adequate chemotherapy.[47,69] The most convincing study to prove this point came from a controlled trials in Madras, India.[70] Newly diagnosed cases of active tuberculosis were randomly allocated to home or sanatorium treatment. Both groups received the same chemotherapy. At the end of 5 years, there were slightly fewer cases among contacts of patients treated at home than among contacts of those isolated in hospital. This result strongly suggests that chemotherapy was as effective as hospitalization in reducing the risk connected with being a close contact of an infectious patient.

When tuberculosis outbreaks occur among people infected with HIV, the dynamics of transmission change considerably because of the telescoping of the period between infection and disease and the great increase in the risk of disease following infection. The explosive nature of such outbreaks is well illustrated by experiences with multidrug-resistant tuberculosis in several hospitals in the United States and in France in the 1980s and 90s[71-73], and in South Africa in 2006.[74]

5.3. Geographic Distribution

Rates of tuberculous infection, disease, and death are highly variable, depending on location (Figure 1). An estimated 8.9 million incident cases of tuberculosis occurred in 2003 and an estimated 1.7 million died of tuberculosis. While case rates have been stable or declining in five of the six WHO regions of the world, the rate is increasing in the African region, due to the high prevalence of HIV infection (Figure 2), and in eastern Europe in response to the collapse of the Soviet Union and the resultant deterioration of public health services. The increases in Africa and eastern Europe have contributed to a net global increase in TB of $\sim$ 1% a year (Figure 3).[2,12,56,57] The 22 high-burden countries account for approximately 80% of all estimated new TB cases each year. China and India alone account for 35%.

Geographic differences measured only by official morbidity statistics may represent not only true differences in the frequency of disease but also diligence in searching for cases,

criteria for diagnosis, and perhaps completeness of reporting. Since its first global survey of tuberculosis in 1997, the WHO has improved our ability to make fair comparisons across the globe.[2]

Tuberculosis case rates for the United States are reported annually by the Centers for Disease Control and Prevention. In 2003, the highest case rates were found in District of Columbia, Hawaii, and California. Cases are more numerous in areas with many immigrants from high-prevalence counties, namely, southern California, areas along the Mexican border, much of Florida, and coastal areas in the northeast. More than 50% of the TB cases reported in the United States are now occurring among foreign-born individuals.[8]

Residence abroad has often been considered to be a significant risk factor for acquiring tuberculous infection. The risks of acquiring tuberculous infection when traveling are based on the same conditions that would apply had the traveler stayed home. The physical condition and vulnerability of the host and the length and extent of exposure would determine the risk.[75,76]

Travel by airplane has been shown to have its own special risks. Passengers sharing airspace for extended periods of time with an individual with active pulmonary TB can become infected within the time frame of the flight. The probability of infection is highest for those sitting closest to the effected individual.[77,78] However, it should be emphasized that transmission of TB on airplanes is extremely rare, and transmission in the community of household is responsible for the overwhelming majority of cases.

5.4. Temporal Distribution

The risk of disease following infection peaks in the first 1–2 years after acquiring infection then declines over time. In the large study of tuberculosis contacts conducted by the US Public Health Service, it was found that the attack rate among tuberculin-positive contacts was 1,000/100,000 during the first year after diagnosis of the index case.[79] Some 8–10 years later, their rate had fallen to 72/100,000 per year, not much higher than rates among tuberculin-positive individuals without a history of household exposure.

The lifetime risk of reactivation TB following latent infection is often estimated at 5–10%, but this depends on the age at which infection was acquired.[36] Data from children

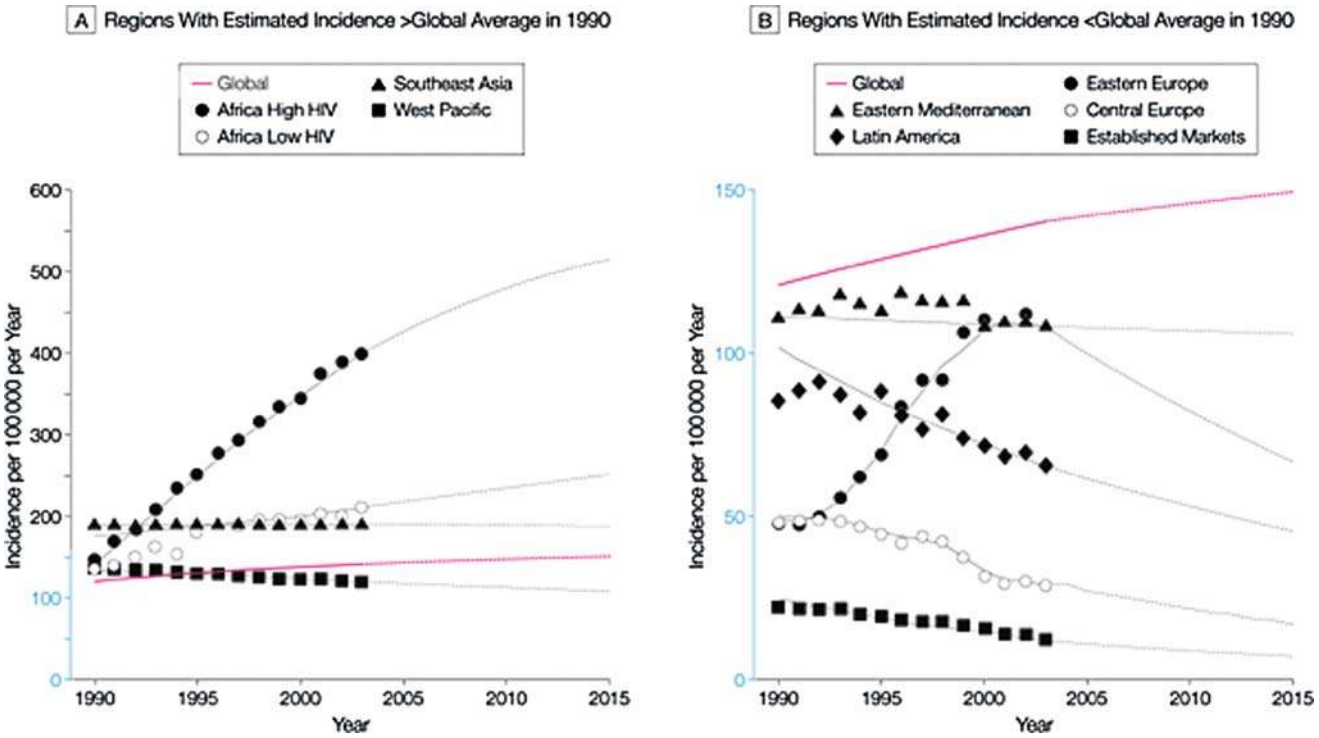

Figure 3. Trajectories of TB epidemic for nine epidemiologically different regions of the world.[2]

with positive tuberculin reactions who were followed for 19 years in Puerto Rico yields a lifetime risk for active TB of 10%, extrapolating linearly. This averaged risk substantially underestimates the risk for some while overestimating the risk for others. Risks vary according to age, co-morbidities, and size of the TB skin test reaction.[80]

5.5. Age

Tuberculosis mortality and morbidity rates show different patterns in populations with high and low risks of becoming infected with tubercle bacilli. Where the risk is high, there is a peak in infancy, followed by a second peak in young adult life, and sometimes a third peak in old age. Where the risk of becoming infected is low, tuberculosis case rates tend to increase steadily with age.[9]

The prevalence of positive tuberculin reactors usually increases at a fairly steady rate with age until about 40–50 years, when it tends to level off or even to fall somewhat. This was illustrated by results of tuberculin testing among New York City school employees in 1973–1974.[81] Determining the incidence of new infections with age is fraught with numerous problems. Most studies agree in finding an increase with age up to about 20 years; estimates of the incidence thereafter vary considerably.[50,82] When current risks of becoming infected are very low, it is likely that reversions from positive to negative may outnumber conversions, especially among older people.

The probability of developing tuberculous disease among positive tuberculin reactors also varies with age (Figure 4).[5,63,83] There is a peak in infancy and early childhood, followed by a second peak in young adult life. The pattern among people past the age of 45 is uncertain because studies of general populations have included only small numbers of infected people this old. It seems likely that the peak in infancy largely reflects the effect of a recent infection, since all infections among infants are necessarily recent. The reason for the increased incidence among infected people in young adult life is not known. The risk of developing tuberculosis at some point during a lifetime for an untreated infected infant is estimated to be approximately 10%. For adults past the age of 25 years, the lifetime risk is considerably lower, being influenced largely by the risk within a year or two after becoming infected.

5.6. Sex

In the United States, tuberculosis death and case rates have been lower among females than among males at almost all ages.[8,9] The differences between the sexes are slight

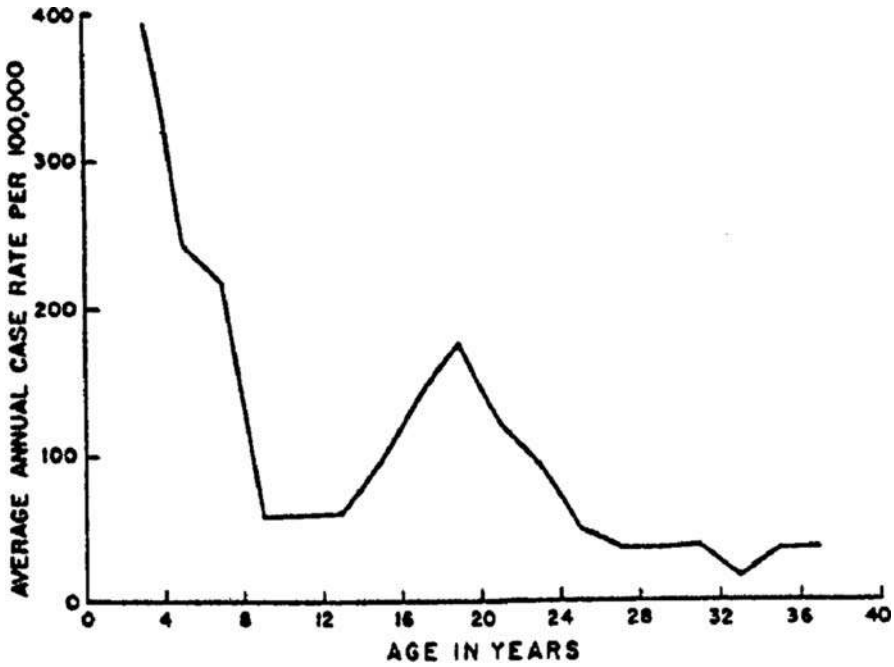

Figure 4. Incidence of tuberculosis disease among tuberculin reactors by age when tuberculosis was first diagnosed.[83]

until 25 years of age, following which male rates rise with increasing age to a greater extent than female rates. The prevalence of positive tuberculin reactors, and presumably the incidence of tuberculous infections, is also lower among females.[9,63]

It is difficult to determine whether the risks are inherent or environmental; and in some settings there are issues of access to care that suggest females with tuberculosis may have lower detection rates.[84,85] There is conflicting evidence regarding the risk of disease among infected males and females. Among Danes, the Alaskan Inuit, young blacks and Puerto Ricans in the United States and refugees in Indochina, rates were higher among females[63,86–88] whereas among whites in the United States and people in South India and Hong Kong, rates were higher among males.[89–91] In a naïve aboriginal population in Paraguay, where case rates were very high, a longitudinal study found no differences in rates of infection and/or disease between males and females.[92]

Most recently, a meta-analysis examined the male to female ratio of smear-positive TB notification rates in 28 high-burden countries. They determined that compared with countries that had a *per capita* cigarette consumption of ≤ 2 cigarettes/day, countries that had a *per capita* cigarette consumption of > 2 cigarettes/day were 78 times more likely to have TB notifications among males exceed those among females by $\geq 70\%$. While these results demonstrated a strong relationship between cigarette smoking and TB, they also provide support for the interpretation of sex differences in worldwide TB notification rates as indicative of true differences in the epidemiology of TB between males and females.[93]

5.7. Genetic Factors and Race

That varying degrees of resistance of tuberculosis can be inherited was clearly shown by Lurie in his work with inbred strains of rabbits.[94,95] The study of individuals with marked susceptibility to mycobacteria usually nonpathogenic to humans in addition to case–control studies using candidate genes and genome-wide screens of affected populations has provided substantial evidence for the role of genetic factors in the susceptibility to mycobacterial disease. Studies of rare mutations in IFN-γ and IL-12 signaling have established the importance of these components of immunity against mycobacterial infection in humans.[96,97]

It is probable that genetic factors are also important in keeping infection from progressing to disease. There have been numerous observations that the risk of tuberculosis among household contacts is greater for blood relatives than for others.[98] That there is a genetic component in this increased risk is indicated by studies of twins, in which concordance for tuberculosis is considerably greater among monozygotic twins than among dizygotic twins, even

when other factors related to tuberculosis risk are taken into account.[99] An additional indication of inherited susceptibility is the report of higher case rates associated with blood groups B and AB among the Inuit in Alaska.[100]

Differences in the presentation of disease also suggest genetic influence. In a study of the characteristics of officially reported tuberculosis cases, several striking differences were found. Alaskans (mostly Inuit and Indians) tended to have limited lesions that were rarely caseating. In contrast, patients from Singapore and from Maryland had extensive disease and a high frequency of cavitary lesions. Patients from five European centers tended to fall between these extremes.[101]

Historically, higher cases rates and deaths have been described among blacks, American Indians, and the Inuit than among whites in the United States.[9] A study of 150,000 nursing home residents in Arkansas in 1990 found that African Americans were twice as likely to develop TB as Caucasians, and this difference was not accounted for by any identifiable social or environmental factors.[102] Death rates have fallen somewhat more rapidly for nonwhites than for whites, while reported case rates have fallen somewhat more rapidly for whites.

Immigrants from developing countries are responsible for ever larger proportions of TB in the United States, Canada, Australia, and western Europe. Evaluating the risks of tuberculosis disease by ethnic group is generally carried out in countries experiencing massive immigration from the developing world.[9,103–107] Immigrants may not be fully representative of a particular ethnic group and the stresses related to their migration may influence their risks of developing TB disease.

5.8. Occupation

An analysis of proportionate mortality among 28 of the United States shows this index to be increased among low-level health care workers, funeral directors, people occupationally exposed to silica dust, and low-socioeconomic-status workers.[108] While mortality is an insensitive indicator of exposure risks, it does have the advantage of being available for all residents of many countries. For the more definitive risks of becoming infected or of developing disease, there is little available evidence with respect to occupation.[109]

Among health care workers, the measured risks vary between settings. In some hospital employees, there were only slight and nonsignificant differences in the frequency of positive tuberculin reactors by type of job or estimated exposure to patients after allowing for the fact that males, minority ethnic groups, and older people all had higher rates of positive reactions.[38] Studies done in New York City and another in the Samara Oblast of Russia evaluated the risk of latent TB infection in settings characterized as low and high risk. They found a significantly higher skin test conversion rate in occupational settings considered high risk over and above the background infection rates found in their respective populations at large.[110,111] Another study showed no increased risk of TB infection for health care workers; risk was explained by income and community, not occupation.[112] There is evidence that hospital physicians in training are not only at increased risk of becoming infected but tend to be uncooperative in tuberculin testing and preventive therapy programs.[113] In Turkey, it was student nurses who were found to be at particular risk.[113,114] The high rate among funeral directors was found to be related to the number of embalming procedures performed and the aerosols produced.[108]

Tuberculosis rates are often excessive in occupations with silica exposure.[115,116] Because silica has been shown to impair host resistance to tuberculosis in experimental animals, it is presumed that people with silicosis also have a reduced ability to control tuberculosis infections.[117] Evidence of the increased rates of tuberculosis among gold miners in South Africa, who are occupationally exposed to silica, appears to confirm that.[116,118–120]

5.9. Socioeconomic Factors

Tuberculosis has long been known to be associated with poverty, crowding, and malnutrition.[4,38] Mortality, morbidity, and prevalence of tuberculosis all tend to be highest in the poorest areas. In Washington County, Maryland, high-school children living in homes with one or more people per room or in an inadequate dwelling as assessed by the absence of complete bathroom facilities were more than twice as likely to be positive tuberculin reactors as children living in less crowded, more adequate dwellings.[121] A more recent study evaluated the association of poverty with TB incidence from 1984 to 1992 in New York City and determined that the relative risk of TB increased approximately 30% per 10% increase in poverty during that time frame.[122]

Relatively few studies indicate whether the risk of disease associated with socioeconomic status results from the risk of becoming infected, of becoming diseased after infection, or both. One of these studies, a report of tuberculin testing of New York City school employees in 1973–1974, showed that the frequency of tuberculous infection was indeed higher in personnel of lower socioeconomic status living in the poorest areas, 22.4%, contrasted with 5.5% in employees in areas with the highest socioeconomic rating, after adjustment for differences in composition by age, race, and sex.[63,81]

5.10. Smoking

In 1956, the British Medical Journal published two articles that discussed the relationship between smoking and pulmonary tuberculosis.[123,124] Doll and Hill made it clear that they had no doubts that there was an association between smoking and mortality from pulmonary tuberculosis, but that the habit of smoking was so strongly associated with social factors also intertwined with the risks of tuberculosis that it was not possible to determine that smoking was an independent risk.

The majority of research focusing on the effects of smoking on the risk of tuberculosis infection and disease has been carried out in recent years, and has been complicated by the likelihood that smoking may also affect delayed hypersensitivity to tuberculin, the very mechanism used to establish the presence of tuberculosis infection.[121,125] Research evaluating the relationship between smoking and tuberculosis disease and deaths has been more convincing. A prospective study carried out in Hong Kong demonstrated that in a cohort of 42,655 elderly people, followed for 2 years, a total of 286 active TB cases were identified. The annual TB notification rates were 735, 427, and 174 per 100,000 among current smokers, ex-smokers, and never-smokers, respectively. The trend in TB risk persisted after adjustment for other risk factors. Among current smokers, those who developed tuberculosis smoked more cigarettes per day than those who did not.[126] In an equally large study examining smoking and mortality in India, smoking was found to contribute substantially to tuberculosis mortality in men aged 25–69 years.[127] A meta-analysis carried out to determine the epidemiological basis for sex differences in TB notifications in 28 high-burden countries determined that cigarette consumption explained 33% of the variance in the sex ratio of TB notifications.[93] Although these studies may not have disentangled all the social factors related to smoking and the risks of tuberculosis, there are reasonable physiologic explanations, and the sheer magnitude of the morbidity and mortality attributed to this association should encourage closer attention to this modifiable risk factor that is associated with so many other health problems.[128]

5.11. Nutrition

For a long time, it has been observed that a variety of situations involving food deprivation are associated with increases in tuberculosis case and death rates.[4,9,21] Since the common factor in these situations is malnutrition, it is likely that the association is one of cause and effect. And since morbidity increases shortly after food shortages appear and decreases promptly when food supplies become adequate, it is likely that the effect of malnutrition is mediated primarily through a concomitant risk of disease among people already infected.

Studies on the importance of specific nutrients have been ongoing since at least the 1950s.[129,130] Epidemiological evidence suggests that vitamin-D deficiency, associated with deficient monocyte-macrophage function, may predispose toward vulnerability to tuberculosis.[131–133] Severe malnutrition has been shown to be associated with a diminution of tuberculin sensitivity following BCG vaccination.[134] There is no indication, however, that malnutrition protects against infection; rather, it appears that it diminishes delayed type hypersensitivity and causes false-negative skin tests.

Body build is related in part to nutrition. Studies among US Navy recruits demonstrated that there is no relationship of relative weight to the prevalence of positive reactions to tuberculin. However, among positive reactors on initial examination, subsequent case rates were nearly four times higher among men who were initially 10% or more underweight than among men initially 10% or more overweight.[26] That body fat was the component of weight likely to be responsible for this association was indicated by evidence from Muscogee County, Georgia. The incidence of disease was closely related to the thickness of subcutaneous fat measured from photofluorograms. Tuberculosis incidence was twice as high among people with less than 5 mm of subcutaneous fat as among those with 10 mm or more.[63]

Two recent placebo-controlled trials looked at whether multi-vitamins, zinc, and/or micronutrients improved treatment outcomes when administered with TB medications.[135,136] There were no dramatic improvements demonstrated in either study. Micronutrients provided a benefit of increased weight gain during treatment, and multivitamins in combination with zinc afforded a survival benefit in those TB patients co-infected with HIV. Both studies were carried out in Mwanza, Tanzania, in TB populations with high HIV co-infection (43%), making it difficult to generalize the findings, despite the elegant study designs.[135,136]

The studies discussed above do not conclusively answer the questions about nutritional status and tuberculosis. Although it is possible that undernutrition causes both leanness and susceptibility to tuberculosis, it is also possible that some other aspect of body build, such as hormonal or genetic factors, is the underlying cause of both. Two findings that favor the latter hypothesis are the impression that very few people in Muscogee County in 1946 could have been considered to be seriously undernourished and the observation among Navy recruits that tuberculosis contacts weighed less than men who had not lived in the same house with a tuberculosis case, even when the comparison was limited to tuberculin-negative people in each group.[137]

5.12. Human Immunodeficiency Virus—HIV

Because of the importance of the cellular immune system in controlling infections with *M. tuberculosis*, it is not surprising that people infected with HIV are at increased risk of both reactivation and primary TB.[138] Linking registers for tuberculosis with those for AIDS has shown that there is a high degree of association, most marked among populations with overlapping risks for being infected with *M. tuberculosis* and HIV (e.g., intravenous drug users in inner cities or residents of some developing countries).[139–141] Populations with a high prevalence of infections with *M. tuberculosis* and HIV have extremely high rates of clinical tuberculosis.[12,138,142–145]

In 2003, Corbett et al. reported the results of an international survey designed to measure the burden of tuberculosis in the context of HIV. They found that approximately 9% of all new TB cases in adults 15–49 years of age were attributable to HIV infection, but the proportion was much greater in African and in some industrialized countries, notably the United States with proportions of 31 and 26%, respectively. An estimated 12% of all TB deaths in 2000 were attributable to HIV, while tuberculosis was the cause of 11% of all adult AIDS deaths. Co-infection with TB and HIV was estimated to be 11 million people, with the greatest proportions being seen in southern Africa. In South Africa alone there were 2 million co-infected adults.[12] Although southern Africa is currently suffering the brunt of these co-epidemics, other regions of the world also have growing numbers of co-infected people. Russia, India, and China and countries in Southeast Asia where the HIV epidemic is newer are home to huge and vulnerable populations.[146,147]

5.13. Size of Tuberculin Reaction

Several studies have shown that people who are most reactive to tuberculin are also most likely to develop tuberculous disease later on (Figure 5).[23,63,148,149] Up to 55 years ago, attention was focused on whether allergy to tuberculoprotein was beneficial or harmful; now, at least in epidemiological circles, principal interest lies in the ability of the degree of hypersensitivity to indicate whether or not the infecting organism was one of the tubercle bacilli, *M. tuberculosis* or *M. bovis*, or one of the usually benign nontuberculous mycobacteria.

The prognostic importance of degree of sensitivity to tuberculin was clearly shown in a study of more than 1 million white Navy recruits.[23] On entry into the Navy, recruits routinely received a skin test with PPD-S and also with a PPD prepared from a nontuberculous mycobacteria, either the so-called Battey or Gause strain, currently named *M. avium-intracellulare* or *M. scrofulaceum*, respectively. Cases of tuberculosis that developed among these men during their first 4 years of Navy service were identified. Recruits with less than 6 mm to 5 tuberculin units of PPD-S on entry had a low rate of tuberculosis subsequently; those with 6–13 mm reactions, an intermediate rate; and those with reactions of 12 mm or more, a high rate.

Both experimental and clinical evidence indicate that reactions to a homologous antigen are usually larger than cross-reactions to a heterologous antigen. Among recruits with intermediate reactions to PPD-S and larger reactions to either PPD-B or PPD-G, the subsequent case rate was essentially the same as recruits with less than 6 mm of induration to PPD-S, suggesting that their reactions to PPD-S were due to cross-reactions from nontuberculous mycobacteria.

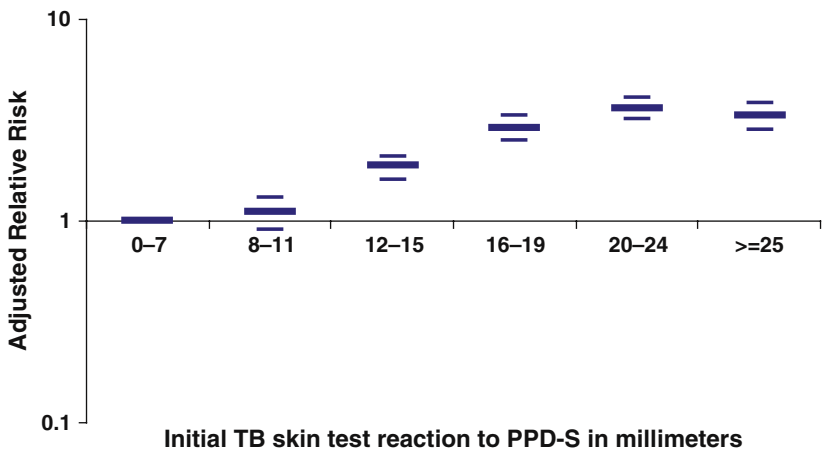

Figure 5. Adjusted relative risk of tuberculosis 0–15 years after the TB skin test by initial reaction size. Adapted from Radhakrishna et al.[149]

In contrast, recruits with intermediate reactions to PPD-S that were clearly larger than those to PPD-B or PPD-G had subsequent tuberculosis case rates that approached those of recruits with large reactions to PPD-S. These and similar findings support the current belief that the larger the reaction to a small or intermediate dose of tuberculin, the more likely it is that an individual has been infected with tubercle bacilli, and consequently the more likely that tuberculous disease will develop at some time in the future.[149] In HIV-infected populations, PPD reactivity continues to be associated with increased risk of tuberculosis disease.[150]

6. Mechanisms and Routes of Transmission

Tubercle bacilli are generally transmitted to humans in only two ways: by the inhalation of tubercle bacilli in droplet nuclei and by ingestion of contaminated milk. Tuberculin testing of dairy cattle and pasteurization of milk had nearly eliminated bovine tuberculosis in the United States and the possibility of its spread to man through dairy products, though recent outbreaks associated with contaminated Mexican cheeses are of concern.[151,152]

When an individual with tubercle bacilli in the sputum coughs, sneezes, talks, or sings, a spray of secretions may be expelled. The larger particles fall out of the air promptly and appear to be of little danger. Tiny particles dry promptly when exposed to air; the resultant droplet nuclei may float with the air currents for a long time and considerable distances.[153] When they are inhaled they can be trapped in the upper air passages or on the ciliated portions of the tracheobronchial tree, but may pass directly to the alveoli. Current evidence indicates that only droplet nuclei that carry tubercle bacilli and reach the alveoli are effective in infecting a susceptible host.

The importance of spread by direct contact, or by ingestion of organisms other than in infected dairy products, is probably slight. Theoretically, communicable droplet nuclei may be generated by manipulation of any material that contains significant numbers of tubercle bacilli. Cutaneous (soft tissue) tuberculosis can be the source of transmission, particularly if the wound is irrigated with a high-pressure system capable of creating aerosol and droplet nuclei.[154] Aerosol respiratory treatments, embalming, and autopsies have all proved their potential to introduce communicable droplet nuclei into the air.[155–158]

Direct inoculation is an unusual method to transmit *M. tuberculosis*.[159,160] Laboratory personnel are at risk from accidental skin punctures with contaminated equipment.[161] Fiberoptic bronchoscopes, inadequately sterilized between patients, have been implicated many times in directly inoculating patients with *M. tuberculosis*.[162,163] Rare instances of sexual transmission of *M. tuberculosis* or *M. bovis* have been suggested where an individual with genitourinary tuberculosis infects a partner.[164]

7. Pathogenesis and Immunity

After tubercle bacilli are inhaled or ingested, they are engulfed by macrophages and carried to the regional lymph nodes, occasionally passing into the bloodstream and thence to many organs of the body. The mycobacteria's waxy cell wall resists attack or digestion; initially it causes little or no reaction in the host tissues. Using mechanisms not fully understood, the engulfed mycobacteria function as intracellular parasites, subverting the phagolysosome so that it can continue to sustain itself with nutrients, but cannot be destroyed, at least temporarily.[165,166]

In a healthy host, the immune system eventually overcomes the mycobacterial interference and within 3–8 weeks, hypersensitivity to antigens develops.[167] Phagocytes that contain tubercle bacilli may then be encased by effector cells; the infected cells are then killed, resulting in foci with central caseous necrosis and a peripheral zone of epithelioid cells, lymphocytes, and fibroblasts. The range of possible outcomes is extremely varied. In many organs and tissues, blood-borne tubercle bacilli show no evidence of becoming established. Bone marrow, liver, and spleen are often involved, but infections in these organs are almost always controlled. More favorable sites for growth are the lungs, kidneys, meninges, and the epiphyseal portions of bone.[168] Even in favorable sites, however, the majority of lesions heal as scar tissue surrounds the caseous foci and tubercle bacilli. Some lesions become partly or wholly calcified. Although the organisms may remain viable for years in these scarred areas, it is likely that most of them eventually die.

In a small proportion of people, the balance tips against the host and in favor of the bacilli. Host resistance may be inadequate from the start, and the infection may progress to active disease; or after an indefinite period of quiescence and apparent healing, the organisms may again start to multiply and destroy tissue. The specific factors responsible for the inability to control the infecting organisms at either time are not yet known. It is known, however, that resistance is lowered in diseases (notably HIV infection) or therapy involving immunosuppression, diabetes, silicosis, and, as noted in Section 5.12, possibly by severe undernutrition.

Not all locations of disease are favorable for the transmission of infecting organisms, since organisms buried in most human tissues will never be excreted in the form of droplet nuclei small enough to be inhaled by another host.

Only in the lungs or especially the larynx is this likely to occur. Actively progressing caseous foci in the lung ultimately erode into a bronchus, the contents are expelled, and a cavity is formed. Tubercle bacilli flourish on the walls of a cavity and can readily pass with the expired air into the atmosphere, where the resulting droplet nuclei may survive to be inhaled into the lungs of another susceptible host.

As mentioned in Section 5, tuberculosis is unlike most other infectious diseases in the extreme variability between the time of infection and development of disease, ranging from a few weeks to a lifetime. When an individual develops tuberculosis disease it may represent endogenous reactivation or exogenous infection or reinfection. This issue is an important one and it is not surprising that it is also controversial.[169]

Individual strains of *M. tuberculosis* can be recognized by restriction fragment length polymorphism analysis (RFLP) or other techniques that identify unique genomic sequences.[170] Patterns made by the fragments, believed to be so unique that this procedure is referred to as "DNA fingerprinting," allow source and subsequent cases of TB to be identified that might otherwise would have been missed.[73,156,170–172] DNA fingerprinting has been useful in determining that the predominant causes of disease may differ in areas of low and high transmission of tuberculosis. Endogenous reactivation of dormant organisms after a period of latency in a previously infected person seems the more common mechanism in areas where the likelihood of infection is low, as in most of the developed world.[173–175] However, community-wide DNA fingerprinting studies suggest a much larger proportion of recent transmission, at least in urban settings, than previously suspected in developed countries.[171,176,177] Exogenous reinfection is disease caused by inhalation of tubercle bacilli by an individual already infected with TB when exposed to a second infectious case. There is evidence that in areas of ongoing TB transmission it is not uncommon for a person with successfully treated tuberculosis to become infected and ill with another strain, apparently inhaled sometime following treatment.[169,178]

There is evidence that initial tuberculosis infection does confer acquired resistance. A study carried out in Norway in 1927 noted that student nurses who began work with positive tuberculosis skin tests were significantly less likely to develop tuberculosis than those students with an initially negative reaction.[179] Similar findings, more recently, continue to support this observation.[180]

There is also evidence that the assumption of acquired resistance does not apply to everyone. One explanation could be that resistance is strain specific. Perhaps some people may not be able to mount a protective immune response against TB whether they have received immunization or been "naturally" exposed; these are people with inherently impaired immune systems.[169,181] What is known is that immunosuppression from HIV or chemotherapy leaves people vulnerable to reinfection despite successful and curative tuberculosis treatment.[180,182,183] It stands to reason that poor nutrition and chronic burdens of parasitic diseases could also leave many people potentially vulnerable in settings with high TB transmission. Greater understanding of the immunologic mechanisms required to acquire and sustain resistance in these settings will be necessary before effective vaccines can be developed.

8. Patterns of Host Response

The type of clinical disease that develops after infection depends to a considerable extent on the ability of host resistance to hold the multiplication of bacilli in check. Some lesions may be small and heal without ever producing symptoms or being recognizable by radiographic or pathological examination. Fortunately, many tuberculous lesions do tend to heal, even after reaching the symptomatic stage. Some, however, progress to a point where tissue destruction is extensive and results in progressive illness and, without treatment, death. The nature of the disease that results from reactivation of an initial lesion or lesions depends most of all on their location. The manifestations of tuberculosis of various organs differ so markedly that it was not until Koch demonstrated the causative organisms that they were accepted as having a common etiology.

While pulmonary disease is the most common presentation, extrapulmonary disease is not unusual. Those who progress rapidly to disease after initial infection have a greater risk of extrapulmonary manifestations, particularly pleural disease. There is evidence that extrapulmonary tuberculosis is more likely to occur in people with immunosuppression, either innate or acquired.[83,184,185] Children appear more likely to develop extrapulmonary tuberculosis, apparently because of immature immunity.[83] A recent study using routine national surveillance data, designed to identify risk groups in the United States, was able to determine that women, non-Hispanic blacks, and HIV-positive TB cases were more likely to manifest extrapulmonary disease.[186] The proportion of tuberculosis cases with extrapulmonary disease increased from 16% in 1990 to 20% in 2000. While the overall rate of new TB cases continues to decline in the United States since national reporting began in 1953, the annual decrease in TB cases has slowed from an average of 7.1% (1993–2000) to the current average of 3.8% (2001–2005), according to CDC. This may be partially explained by the increasing proportion of foreign-born indi-

viduals with TB, who also have disproportionate rates of HIV infection.[8]

9. Control and Prevention

9.1. General Concepts

The behavior of TB in populations suggests that evolution of host resistance may be important in reducing the incidence and deadliness of the disease. When TB enters a naïve population, case rates and mortality are initially very high, then gradually decline over a number of generations. Historians have noted that the decline in tuberculosis in many countries appears to have started before the discovery of the tubercle bacillus, and hence prior to any measures specifically designed to control the disease. Others have pointed out, however, that improved living and working conditions brought about by the sanitation and social reform movement of the 1800s might well have helped produce a decline in tuberculosis.[4] In particular, improved ventilation and daylight in houses and places of employment should have decreased the probability of becoming infected, while shorter work weeks and improved nutrition should have increased resistance to disease. It seems likely that improvements along these lines contributed to the decline of tuberculosis.

Tuberculosis control measures among humans fall into four major categories: decontamination of air and milk, case-finding and chemotherapy, treatment of latent TB infection, and vaccination. Each has its advantages and disadvantages, and each has a place under the appropriate circumstances. A simple model serves well to illustrate how each of these control measures affects the tuberculosis problem.[187] The major elements of the model are shown in Figure 6, adapted from Shirley Ferebee's model first published in 1967. Missing from the figure's portrayal of a 1-year cycle is the reduction of the uninfected and infected populations by deaths and the addition to the uninfected population by births.

In any given year, a certain number of cases develop from previously infected people. Each of these cases infects others, some of whom develop tuberculosis during that year and others of whom are added to the infected group for the subsequent year. These new cases in turn infect others, who are also added to the infected group. As you will see in the following discussion, *if* the effectiveness of tuberculosis control could be maintained, tuberculosis would eventually disappear, although this would require many years.

9.2. Decontamination of Air and Milk

When pulmonary tuberculosis patients are identified, precautions should be aimed at preventing air from becoming a vehicle of infection. The formation of infectious particles can be markedly reduced merely by covering the mouth and nose when coughing or sneezing. The patient should be taught to cover the mouth and nose with disposable tissues when coughing or sneezing in order to trap droplets before they can evaporate and become free-floating droplet nuclei. Initiating treatment rapidly reduces the infectivity of patients and is the most important intervention for protecting others from infection when TB patients are hospitalized. There should be good ventilation in the room without recirculation of air; preferably, the air should be exhausted directly to the outside and the room kept under negative pressure. Ultraviolet irradiation of the upper air or of recirculated air is also helpful. High-efficiency particulate (HEPA) masks or respirators are strongly encouraged for use by all personnel caring for infectious tuberculosis patients.[188,189]

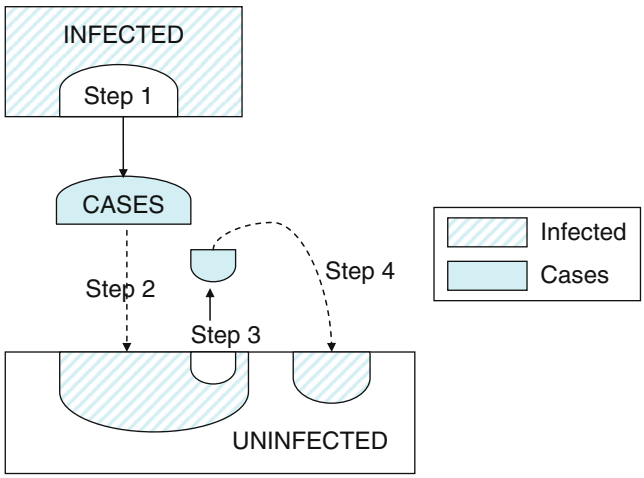

Figure 6. Schematic illustration of annual cycle of development of tuberculosis infection and disease. Adapted from Ferebee.[187]

In the occasional instances when explanation and persuasion fail and a patient with infectious tuberculosis refuses to take the necessary steps to protect others, it is possible in the United States and some other developed countries to use legal means to enforce isolation.[190,191] These measures are not accepted universally.[192] In areas of endemic tuberculosis there is often no cultural imperative to quarantine contagious individuals, as it is assumed that many people are already infected and thus not at risk or are protected by the BCG vaccination administered at birth so that forced isolation is believed to be both unnecessary and cruel.

The major means of keeping milk from being a vehicle of infection are periodic tuberculin testing of dairy cattle, slaughter of reactors, and pasteurization of milk. Although tuberculosis among cattle has been nearly

eliminated from the United States and milk-borne tuberculosis has become rare, this near success has led to diminished funding for the elimination program, laxity in tuberculin testing, and renewed interest in drinking raw milk, all of which could lead to milk again becoming a source of tuberculous infection. Recent cases of *M. bovis* in children that consumed non-pasteurized Mexican cheeses in New York City underscore the importance of vigilance in this area.[151]

If by some miracle both air and milk could be kept completely free of tubercle bacilli, the cycle of tuberculosis shown in Figure 6 would be blocked at Step 2. Tuberculosis would continue to develop among the previously infected population until all infected people had died.

9.3. Case-Finding and Chemotherapy

Similarly, in an ideal but unfortunately imaginary world, case-finding endeavors would identify every case before it became infectious and chemotherapy would be completely effective in preventing future infectiousness. Such perfection would also block the flow of tuberculosis at Step 2 in the model shown in Figure 6. As noted before, cases would continue to develop from the pool of infected people until all had died of TB or other causes.

Case-finding in developed countries is now difficult because the prevalence of cases has become so low that mass screening procedures are unproductive and the index of suspicion of most medical practitioners is low. In developing countries, where mass screening methods could be more useful but usually cannot be afforded, microscopic examination of stained specimens of sputum from people with chronic cough has been shown to be effective in identifying the most infectious cases; the impact on disease incidence has been mixed. In Peru, this strategy has led to a sharp decline in incidence, while in Vietnam it has not.[193] In both developed and developing countries, the most appropriate combination of diagnostic modalities—medical history, skin testing, chest radiography, and bacteriology—will need to be selected after reviewing the local tuberculosis problem and the resources to combat it.[194,195] In settings with a high prevalence of HIV infection, there is evidence that active TB case-finding, with initial screening tools as basic as a questionnaire, can yield high proportions of active cases.[141,196–199] Chemotherapy has become so effective that virtually every patient with organisms sensitive to the standard antituberculosis drugs could be cured if the necessary medications were taken conscientiously. Not only can the disease be cured, but patients are also quickly rendered noninfectious by the generally accepted chemotherapeutic regimen. This consists of the daily administration of four drugs—isoniazid, rifampicin, pyrazinamide, and ethambutol—for 2 months, and two drugs—isoniazid and rifampicin—for another 4 months.[200]

While this regimen may be simple from a medical point of view, the toxicity, duration of the regimen, and competing interests and needs can cause some patients to discontinue treatment prematurely or take it irregularly.[201–206] Interruption and discontinuation of treatment can lead to the resumption of TB transmission, and in some cases to the development of drug resistance.[207–210] The emergence of drug-resistant organisms necessitates expert administration of expensive and toxic drugs. Even then, the prognosis is often unfavorable. Treatment success for patients with multidrug-resistant tuberculosis requires 18–24 months of therapy and treatment success ranges for 45–75%.[211,212]

In 2000, in the United States, 56% of the 16,372 reported cases had pulmonary tuberculosis with known positive sputum; it is theoretically possible that with further examinations, all of the pulmonary cases (80%) might be classified as communicable. Of the 15,784 with any form of tuberculosis who were started on chemotherapy in 2000, 1,103 were known to have died (from any cause). Fewer than 85% of the others were known to have completed a recommended course of therapy.[8] Although it has improved over the years, even better performance is needed if the United States hopes to eliminate tuberculosis by case-finding and chemotherapy within the next few decades.

Directly observed therapy (DOT) is a strategy to promote treatment adherence and to reduce the development of drug resistance.[213,214] There have been many adaptations and enhancements to the strategy, but the basic idea is to provide support and supervision to TB patients during the long course of their treatment.[215–222] Studies carried out in Singapore and Hong Kong demonstrated that intermittent therapy—twice or three times weekly—was as effective as daily medication, making DOT more practical and affordable.[223,224] There is controversy about the necessity of literally observing patients take medication, but there is consensus in the TB control community that the other four points in the system defined by WHO as directly observed therapy short-course (DOTS) (Figure 7) are necessary and appropriate for TB control.[225] Evidence of the effectiveness of DOTS is that although global TB incidence rate is slowly rising, prevalence and death rates are falling.[56] Attention to administrative details and directly observed intermittent regimens can all contribute to better patient acceptance of treatment, to a high rate of cure, and to prevention of the emergence of drug-resistant strains.[217,220,226]

Five Components of the DOTS Strategy

- Government commitment to sustained TB control activities.
- Case detection by sputum smear microscopy among symptomatic patients self-reporting to health services.
- Standardized treatment regimen of 6-8 months for at least all confirmed sputum smear positive cases, with directly observed treatment (DOT) for at least the initial 2 months.
- A regular, uninterrupted supply of all essential anti-tuberculosis drugs.
- A standardized recording and reporting system that allows assessment of treatment results for each patient and of the TB control program overall.

Figure 7 World Health Organization strategy of directly observed therapy short-course.[221,222]

9.4. Preventive Therapy

Following the introduction of isoniazid as a chemotherapeutic agent against tuberculosis, Edith Lincoln, then the dean of the tuberculosis experts in the United States, noted that children with primary tuberculosis treated with this drug showed a much lower incidence of serious tuberculous complications than had been noted with other medications and suggested that a controlled trial of the effectiveness of isoniazid in preventing these complications be undertaken.[79] The ensuing trial among 2,750 children with asymptomatic primary tuberculosis or recent tuberculin conversions showed treatment with isoniazid to be remarkably effective, producing a 94% reduction in tuberculous complications during the year of preventive treatment and a 70% reduction over the subsequent 9-year period. Fears that the preventive use of isoniazid would lead to the emergence of isoniazid-resistant strains of tubercle bacilli have not been borne out.[79]

At least 21 controlled trials of preventive therapy with isoniazid involving more than 136,000 subjects have now been reported.[227,228] Among 14 trials with more than 1,000 subjects, the median reduction in tuberculosis from preventive treatment was 60% during the periods of observation, which ranged from 1 to 13 years. The range of effectiveness in these 14 trials was 25–88%. The trials with low effectiveness included one that used small doses of isoniazid and one in which adherence was very poor. It should be noted, however, that these estimates are based on the total study populations regardless of how well medication was taken. People with high adherence tended to obtain greater protection than the preceding median values indicate. Among people who adhere well to the treatment regimen, 12 months of medication has been shown to be more effective than 6 months.[229] Studies among tuberculosis contacts and Alaskan villagers show that 9 months of treatment is optimal.[79,230]

Some degree of protection can be expected to be long-lasting. Any diminution caused by isoniazid in the numbers of tubercle bacilli harbored by the host increases the probability that host resistance can control any organisms that may remain. In addition, it has been shown that a treated infection in guinea pigs confers some resistance against subsequent reinfection.[231] Protection in humans has been shown to persist for at least 10–19 years.[79,232]

The principal appeal of treatment for latent TB infection lies in its ability to interrupt the chain of infection at Step 1 in the model shown in Figure 6. Universal application to reactors and perfect effectiveness of this preventive procedure could theoretically eradicate tuberculosis almost at once. While realism does not allow hope of even approaching such an outcome, whatever effectiveness preventive treatment may have affects every step in the model and not merely the later ones. Of considerable current interest is the evidence from observational and controlled studies that preventive treatment with isoniazid not only reduces the risk of tuberculosis among HIV-infected people but may also delay the onset of symptoms of AIDS.[138,228,233] Treatment with isoniazid following a full course of curative TB therapy provided continued protection in HIV-positive people.[234]

Other preventive regimens have been evaluated, largely to determine whether shorter regimens using other antimycobacterial drugs are equivalent to therapy with isoniazid. A 2-month drug regimen of pyrazinamide and rifampin had promising results in trials enrolling HIV-infected adults, but for reasons still not fully understood, the increased hepatotoxicity of the regimen was responsible for the deaths of HIV-uninfected individuals in the United States, curtailing its use.[235–238] The use of rifampin is recommended when it is known or suspected that the infection is due to an isoniazid-resistant strain of TB, but isoniazid continues to be the backbone of the treatment for latent tuberculosis infection.[36]

A comprehensive review of 11 randomized controlled trials of TB preventive therapy regimens, evaluating a total of 8,130 HIV-infected participants, determined that TB preventive therapy, regardless of regimen, was associated with a significant reduction in the subsequent development of active tuberculosis. The effect was more pronounced in those people with a positive TB skin test than those with a negative test. The length of the protective effect was variable. Each of the drug regimens was equally efficacious, although those individuals who received isoniazid were less likely to suffer adverse effects.[239] It is recommended that a person who tests positive for HIV be tuberculin tested; if there is

induration of 5 mm or more to 5 tuberculin units of tuberculin PPD, preventive therapy with isoniazid is strongly advised.

9.5. Immunization

Immunization against tuberculosis is currently limited to the use of BCG (bacille Calmette–Guérin), an attenuated organism named for the two French investigators responsible for its development.[4] Working with *M. bovis* in 1908, they added bile to their culture media in an effort to obtain well-dispersed suspensions of the organisms. As an unexpected result, they noted that the organisms cultured in this way lost virulence for laboratory animals. After 13 years of subculturing and testing, they became convinced that they had developed a strain of organisms that would remain avirulent and could be used to immunize humans against tuberculosis.

BCG has probably had more, larger, and possibly better-controlled trials of its usefulness and effectiveness than almost any other preventive measure. Despite this, there is marked disagreement about its effectiveness. A meta-analysis of 15 of the 16 controlled trials of intracutaneous BCG vaccination concluded that the average efficacy was 50% (range –56 to +80%).[240] It was concluded that much of the variability was due to latitude, a surrogate for the prevalence of nontuberculous mycobacterial infections, with the least protection at lower latitudes. Although the possibility was discounted that some of the variability in results might be associated with differences in BCG strains, characteristics of BCG vaccines can change with continued cultivation. To some, this seems a likely explanation for the marked differences observed among the results of various trials done around 1950 with different substrains of vaccines that were then more than 25 years removed from the original parent strain. With the lapse of 40 or more years since these trials, reliable information is lacking on the effectiveness of currently available strains. That some strains of BCG do differ in efficacy is indicated by the findings in each of two case–control studies of marked differences in effectiveness when one vaccine was substituted for another[241] and in a recent controlled trial of two different BCG strains.[242,243] It has recently been shown that currently available BCG strains differ in their genetic makeup.[244] Unfortunately, there is currently no way other than long-term studies to assess efficacy of the strains. Postvaccinal tuberculin sensitivity is not related to efficacy and animal models are variable and cannot be used to predict responses in humans.[241]

Because of uncertainties regarding the efficacy of most BCG vaccine strains, the decision on the use of vaccination must depend in part on the availability of other means of tuberculosis control. In much of the world, the decision is not difficult. In countries with a very low infection rate, such as the United States, with a readily available alternative program of tuberculosis control by case-finding, chemotherapy, and preventive therapy, there is very little need for the kind of protection that vaccination can give and considerable reason to protect the usefulness of the tuberculin test.[245] As a result, in the United States BCG vaccination is recommended only for tuberculin-negative people at a high risk of becoming infected for whom no other method of tuberculosis control is feasible. Its use is contraindicated in people with or at high risk of being infected with HIV, because the vaccine can cause localized or disseminated disease in immunocompromised people.

In many other countries, there is clearly a high risk of tuberculosis infection, especially in infants, and little prospect of effective control except by BCG vaccination. In such situations, vaccination programs must be continued, except among people with known HIV infections. Preliminary tuberculin testing is not needed for vaccination of newborn infants. Nor is skin testing necessary for vaccination programs aimed at older people, since it has been shown that vaccination of tuberculin-positive people and people with tuberculosis did not result in demonstrable harm.[246]

The vaccine is inexpensive, its administration is simple, and vaccination probably does not have to be repeated. Serious complications are very uncommon.[247,248] However, vaccination does produce localized ulceration that can persist for several months and may be accompanied by local lymphadenopathy. A potentially important side effect is the production of sensitivity to tuberculin. In areas with a high risk of infection, most people will become tuberculin reactors in the course of time, and the premature production of tuberculin sensitivity by vaccination is of little consequence. In areas with a low risk of infection, the help that the tuberculin test can give diagnostically and prognostically constitutes an added contraindication of BCG vaccination. Also in these areas, the reports of a long-term risk of lymphomas associated with vaccination in two of three trials should not be ignored.[243,249]

The role that effective immunization might play in the control of tuberculosis is also indicated by the model in Figure 6. As was the case for case-finding and chemotherapy (Section 9.3), the effect of immunization is on Step 2, namely protecting the uninfected population against development of disease when exposed to infectious cases. Universal application of a vaccine with 100% efficacy would not eradicate tuberculosis until all infected reactors had died.

Do you want to indicate the length of protection by use of BCG as it provides protection against spread in children but not infections?

10. Unresolved Problems

Tuberculosis is increasing today at a worldwide average rate of 1% a year. There are many important issues that need to be resolved to turn the tide and successfully control tuberculosis. Perhaps the most important, the element that is essential but not sufficient, is political will. The eradication of smallpox is a proud example of what can be accomplished in seemingly impossible circumstances when there is political will, much as the English proverb says, "Where there's a will, there's a way."

Reducing the risk of infection and subsequently the risk of developing TB disease are problems for which there are solutions, if there is the will to carry them out. Improving the general living conditions of millions of impoverished human beings who populate this earth would reduce the risks of infection by diminishing exposure from overcrowding and bolstering immune response through improved nutrition. Instituting the universal habit of covering the mouth with a cloth or tissues, when coughing, or coughing into the elbow will reduce transmission. Instituting and enforcing the isolation of suspected TB patients and simultaneously taking measures to protect health care staff will further reduce transmission. The risks of transmission come from those TB cases that are not yet recognized and that have not started treatment. There is ample evidence that once treatment begins, the risks of TB transmission are small to nil; the risks of transmission come from individuals that are not yet suspected of having TB.[48,250]

Reducing the risk of infection with HIV will help to reduce the pool of individuals with exceptional vulnerability to tuberculosis infection and disease. Once infected, all individuals with HIV should have the opportunity to learn their infection status, and must have access to medications that will prevent opportunistic infections (including tuberculosis), treat their HIV infection, and reduce their risk of dying.

Development of a TB vaccine with known efficacy would be of great use. Protecting individuals at birth from the risk of infection with tuberculosis would be ideal. Currently, there is uncertainty about the efficacy of BCG strains in use. BCG has been protective in some populations, so it will be important to fully understand which BCG strains are protective and why.

Development of a sensitive test that could easily and reliably identify infected people who still harbor living tubercle bacilli would permit truly targeted prevention of active tuberculosis; only those with active infection would require, and benefit from, treatment. The present tuberculin skin test and serological tests fail on two counts: (1) positive reactions can be caused by mycobacteria other than *M. tuberculosis* or *M. bovis* and (2) reactions from a tuberculous infection may persist long after the infecting organisms have succumbed to the host's defenses. Improvement of the tests on either count would make both diagnosis and preventive therapy much more efficient. Long-term follow-up studies of people who have positive interferon-gamma release assays are needed to determine the prognostic potential of these new immune-diagnostic tests.

The length of an effective course of TB treatment, despite the name "short-course," is still too long. Six months of treatment is expensive and difficult to maintain for TB patients and their care providers. Although cure rates of 95% are encouraging, the risk of failure which seems small when expressed as a percentage still leaves adequately treated patients as a high-risk group. This becomes obvious when a failure rate of 5% is expressed as 5,000/100,000. The development of truly short, effective, and non-toxic regimens will be essential to improve the rates of treatment completion and cure. The availability of such drugs is only half of the story; TB patients must have access to them as well. Clinics must be within reach and medications must be free of charge.

Drug-resistant tuberculosis is a major control issue in some parts of the world. Ironically, how to prevent tubercle bacilli from becoming resistant has been known for decades. Completing an effective, multidrug regimen is the best way to keep the emergence of drug-resistant organisms to a minimum. Too often, drug resistance is the result of a lack of TB control due to a lack of finances and poor administration. Without consistent support, patients may be selective in which medications they take, leading to the development of strains no longer killed by the drugs used in standard short-course therapy. The same result occurs when a clinician prescribes inappropriate or incomplete drug regimens and when drug supplies are interrupted, because patients' funds run out or from inadequate distribution systems.[210,251–253] The resultant irregular or ineffective treatment allows drug-resistant organisms to emerge, to spread to others, and to be treatable only with more toxic and longer regimens. Even in the best of circumstances, treatment outcomes are frequently poor for those afflicted with multidrug resistance—a strain of TB that is not killed by either isoniazid or rifamycin.[254]

The tuberculosis pandemic has received international attention, and along with HIV and malaria has become the catalyst for unprecedented collaboration between the private and public sectors.[255,256] Tuberculosis control requires not only financial but human resources. It has finally been recognized that the only realistic method of garnering these resources is through creative collaboration between the public sector, nongovernment organizations, and corporations. The World Health Organization followed such a model when

it created the Global Partnership to Stop TB in 2000. Comprised of international organizations, countries, donors from the public and private sectors, governmental and nongovernmental organizations, and individuals, Stop TB now boasts 400 Partners from around the world. One of the Partnership's great accomplishments has been the development of the Global Drug Facility that helps countries obtain, manage, and distribute affordable and good-quality drugs. Most recently the Stop TB Partnership has published the Global Plan to Control TB, an ambitious and meticulously detailed blueprint for actions needed to reduce TB prevalence and death by 50% by 2015.[257] Founded in 2001, the Global Fund to Fight AIDS, Tuberculosis and Malaria is a unique, private financing mechanism that attracts money from governments, foundations, corporations, and individuals that it then manages and disperses through existing agencies and by awarding grants. Only time will tell whether our will is strong enough to see our way to truly effective international TB control.

CHAPTER 41

Nontuberculous Mycobacterial Infections

Charles L. Daley

1. Introduction

The nontuberculous mycobacteria (NTM) comprise over 125 different species that are widely distributed throughout the environment.[1] Over the decades the NTM have been referred to as mycobacteria other than tuberculosis (MOTT), atypical mycobacteria, and environmental mycobacteria. Despite their frequent isolation in the environment and human specimens, the NTM were not widely recognized as a cause of human disease until the late 1950s. Since that time, the number of new species of NTM has grown dramatically primarily related to the availability of DNA sequencing, which has allowed identification of new species simply by detecting relatively small differences in DNA sequences. In addition to the proliferation of new species, the rate of disease related to NTM has also increased in some areas.

NTM have several features that distinguish them from organisms in the *Mycobacterium tuberculosis* complex. The NTM display a wide range of pathogenicity and unlike *M. tuberculosis*, they are not transmissible from human to human. Many of the pathogenic NTM are relatively drug resistant compared with *M. tuberculosis*, and thus, they are difficult to treat with high rates of treatment failure and recurrence. Because of our poor understanding of the transmission and pathogenesis of most NTM infections, we have little insight into how to prevent these infections and thus our public health strategy to control disease caused by these organisms is limited.

Charles L. Daley • Division of Mycobacterial and Respiratory Infections, National Jewish Medical and Research Center and the University of Colorado Health Sciences Center Head, Denver, Colorado 80206, USA, e-mail: daleyc@njc.org.

2. Historical Background

NTM have been recognized since the late nineteenth century when "tuberculosis" in birds was described prior to the isolation of the human tubercle bacillus.[2] As these organisms did not cause characteristic disease when inoculated into guinea pigs, they were recognized as distinct from *M. tuberculosis* and were not believed to cause disease in humans. The recognition that these organisms caused human disease was described as early as 1893,[3] and numerous reports supporting their role as a true pathogen appeared subsequently.[4,5]

By the 1950s, pulmonary disease due to NTM became more commonly recognized and accounted for approximately 1–2% of admissions to tuberculosis sanatoriums in the southeastern United States.[6] In 1954 Timpe and Runyon classified these "atypical" mycobacteria into four groups based on simple culture characteristics: (1) photochromagens (group I), which develop yellow or orange pigment when exposed to light; (2) scotochromagens (group II), which form orange-yellow pigment in the dark; (3) nonchromogens (group III), which are unpigmented; and (4) rapid growers (group IV), which grow on culture media within 7 days. This latter group is distinguished from the slow-growing mycobacteria, which usually takes 3–6 weeks to grow.

Interest in NTM increased when HIV-infected patients began to develop disseminated infections due to various NTM species, particularly *M. avium*.[7–11] As antiretroviral drugs became available, the incidence of disseminated MAC decreased but we are now seeing an increase in the number of cases of pulmonary disease due to NTM particularly among older Caucasian women.

3. Methodology

3.1. Sources of Data

Infections due to NTM are not reportable to public health authorities in most countries, including the United States. Therefore, surveillance data are seldom available. Most studies that have described the epidemiology of NTM can be broadly divided into three types: (1) skin test studies; (2) laboratory-based microbiologic studies; and (3) studies with clinical correlation.[2] The latter studies are the most useful because they combine information from the mycobacterial laboratory and the clinician's assessment; however, there are relatively few of these studies available.

3.2. Laboratory Diagnosis

3.2.1. Isolation and Identification of NTM. The bacteriological diagnosis of NTM is based on isolation of these organisms from diagnostic specimens using standard mycobacteriology laboratory techniques. All cultures should include both solid and broth media for detection of mycobacteria and a semi-quantitative reporting of colony counts is recommended.[1] Several mycobacterial species, including *M. haemophilum, M. genavense, M. avium subsp. paratuberculosis,* and *M. ulcerans*, require special supplementation for recovery on culture.

The optimal temperature for most cultures of NTM is between 28 and 37°C although some species require either higher or lower temperatures for optimal growth.[1] Most NTM grow within 2–3 weeks on subculture although *M. ulcerans* and *M. genavense* may require at least 8–12 weeks and rapidly growing mycobacteria usually grow within 7 days of subculture.

Species-specific identification of NTM has become increasingly important because of the variation in antimicrobial susceptibility and treatment options. Identification can be based on phenotypic, chemotaxonomic, and molecular methods.[1] NTM can be categorized by their growth rate and pigmentation although these characteristics are not specific enough for final speciation. Isolates which form colonies within 7 days of subculture are referred to as rapidly growing mycobacteria whereas those that take longer than 7 days to form colonies are referred to as slowly growing mycobacteria. As noted earlier, the NTM can be divided into three groups based on the production of pigment. In addition, biochemical testing can be used to help speciate the NTM. However, none of these procedures are sufficient to differentiate all NTM, particularly some of the newly identified species.[12–14]

Along with traditional techniques, the modern clinical laboratory includes a broad variety of rapid methods for mycobacterial speciation including nucleic acid probes, polymerase chain reaction and other amplification methods, high-performance liquid chromatography (HPLC), and nucleic acid sequencing.[15–24]

The commercially available AccuProbe technology (Gen-Probe, San Diego, California) is currently recommended for identification of *M. tuberculosis* complex, *M. avium* complex (as well as *M. avium* and *M. intracellulare* separately), *M. kansasii,* and *M. gordonae*. This method, which targets 16S rRNA in the organism, requires a substantial amount of bacteria, and thus, it takes at least 3 weeks for cultivation on agar medium or 10–12 days in a liquid medium to achieve sufficient growth for this test.

HPLC, which analyzes the chromatographic profile of the mycolic acids extracted from the bacterial cell wall, is a highly sensitive method that can detect at least 63 chromatographic patterns representing 73 mycobacterial species.[19,20,22,25] A much broader range of species can be reliably identified by combining information from the HPLC test results with other data, such as growth requirements, growth rate, colonial morphology, and pigmentation.

Identification of mycobacteria by 16S ribosomal DNA sequencing[17,21,23,24] provides more accurate determination of the species although not all species can be differentiated by this method. The procedure includes disruption of the bacterial cells, followed by amplification of a 1 kb fragment of 16S ribosomal DNA. The species identification is based on a comparison between the sequences obtained and those in the libraries of already known species. The supplies for the test and the libraries are commercially available in an automated format (MicroSec 500 16S rDNA Bacterial Sequencing Kit system from Applied Biosystems, Foster City, California).

3.2.2. Drug Susceptibility Testing. There is continued controversy regarding the clinical usefulness of drug susceptibility testing in the management of patients with NTM. This controversy stems from the fact that the in vitro results do not correlate well with clinical outcomes for some mycobacterial species.

For slowly growing mycobacteria there is no single susceptibility method that is recommended for all species. For MAC, a broth-based culture method with both microdilution and macrodilution methods is considered acceptable.[1] Initial isolates should be tested for clarithromycin as well as isolates from treatment failures and relapses, those who have taken macrolides previously, and AIDS patients who develop bacteremia on macrolide prophylaxis.[1] Testing of other drugs may be useful when trying to select additional drugs for treatment of patients with MAC, especially in patients

who are failing therapy, have relapsed, or have macrolide-resistant disease.

Isolates of *M. kansasii* should be tested to rifampin as resistance to rifampin is associated with treatment failure/relapse. If rifampin resistance is documented additional drugs should be tested including amikacin, fluoroquinolones, macrolides, ethambutol, sulfonamides, and isoniazid.

Broth microdilution MIC determination for susceptibility testing is recommended for rapidly growing mycobacteria and inclusion of the following drugs is recommended: amikacin, kanamycin, tobramycin, imipenem, doxycycline, clarithromycin, azithromycin, trimethoprim/sulfamethoxazole, augmentin, cefoxitin, ciprofloxacin, moxifloxacin, tigecycline, and linezolid.

3.2.3. Serological and Immunologic Tests. Delayed-type hypersensitivity reactions to mycobacterial antigens can be detected in patients who have been infected with NTM. Similarly, most patients with evidence of NTM disease also demonstrate serological responses to infection.[26] A recent study evaluated an enzyme immunoassay (EIA) kit for the diagnosis of pulmonary MAC disease.[27] The assay detects serum IgA antibody to glycopeptidolipid core antigen specific for MAC. Antibody levels were measured in 70 patients with MAC lung disease, 18 with MAC "contamination", 37 with pulmonary tuberculosis, 45 with other forms of lung disease, and 76 healthy controls. Significantly higher serum IgA antibody levels were detected in patients with MAC pulmonary disease compared to other groups ($p < 0.0001$). Significantly higher IgA concentrations were also detected in patients with nodular bronchiectasis disease compared to fibrocavitary disease ($p < 0.05$), and there was a correlation between antibody levels and the radiographic extent of disease ($p < 0.05$). The sensitivity of the assay was 84.3% and the specificity 100% for detection of MAC lung disease.

A first-generation interferon-gamma release assay (QuantiFERON TB Test, Cellestis) included MAC PPD in the test, but data regarding the utility of this assay in the diagnosis of MAC lung disease are lacking. In one of the first studies evaluating the QuantiFERON test, reactivity to MAC PPD was associated with discordance between the tuberculin skin test and the QFT-TB results, suggesting underlying MAC infection was causing false-positive tuberculin skin test results.[28] In a study that performed QFT and skin testing with PPD-B in injection drug users, the authors reported poor concordance between the tests (63%)[29]. Additional studies will be needed to access the clinical utility of these types of assays.

4. Biological Characteristics of the Nontuberculous Mycobacteria

Mycobacteria belong to the order of Actinomycetales.[30–32] In 1998, there were 71 described species of the *Mycobacterium* genus but today there are at least 125

Table 1. Slowly and Rapidly Growing NTM Reported to Cause Disease in Humans

Slowly growing mycobacteria		Rapidly growing mycobacteria	
M. alsiense	*M. lentiflavum*	*M. abscessus*	*M. confluentis*
*M. avium**	*M. malmoense*	*M. chelonae*	*M. cosmeticum*
M. asiaticum	*M. marinum*	*M. fortuitum*	*M. elephantis*
M. bohemicum	*M. nebraskense*	*M. mucogenicum*	*M. goodii*
M. branderi	*M. parmense*	*M. peregrinum*	*M. hassiacum*
M. chimaera	*M. parascrofulaceum*	*M. porcinum*	*M. immunogenum*
M. celatum	*M. palustre*	*M. senegalense*	*M. mageritense*
M. conspicuum	*M. saskatchewanse*	*M. bolletii*	*M. novocastrense*
M. doricum	*M. scrofulaceum*	*M. brumae*	*M. septicum*
M. florentinum	*M. sherrisii*	*M. canariasense*	*M. thermoresistible*

separate species that have been reported.[30,32–34] The rapid expansion in the number of mycobacterial species is in part related to the availability of new methods that can differentiate new species at the molecular level.

The pathogenicity of the various NTM species varies greatly, from organisms that are seldom pathogenic to humans such as *M. gordonae,* to those that are almost always disease producing, such as *M. kansasii*. The biologic reason for this wide spectrum of pathogenicity is poorly understood.

As noted previously, NTM are typically divided into rapidly and slowly growing mycobacteria based on their ability to produce visible colonies on solid culture medium at the optimal conditions in less or more than 7 days (Table 1). In addition, the various species can be classified by the presence or absence of pigmentation as described in the Runyon and Timpe classification. Based on isolation from patients in whom the isolate was identified as a pathogen, at least 30 organisms among slowly growing mycobacteria are considered potential pathogens. In addition, other slow-growing mycobacteria that are not considered definitely "pathogenic" for humans can be found in diagnostic specimens often from environmental contamination. Similarly for rapid growers, a minority of the known species have been reported to cause disease in humans.

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

Cutaneous delayed-type hypersensitivity to mycobacterial antigens has been used to assess the frequency of infection with *M. avium* and *M. intracellulare* and has demonstrated that a substantial proportion of adults have had prior exposure to MAC. Between 1943 and 1959, 22,000 nursing students were tested with 5 tuberculin units of PPD-S.[35] Students who did not react to 5 tuberculin units were retested with 250 units to detect reactivity to cross-reacting antigens. Sixty-five percent of students who came from the southeastern United States reacted to the higher dose of tuberculin compared with only 29% of those from other areas of the country, suggesting a high rate of infection to MAC and possibly other NTM species. Similarly, skin test surveys of U.S. Navy recruits in the 1960s documented higher rates of reactivity in those from the southeastern United States (56%) than from the northern states (15–25%).[36]

Microbiological survey data from state laboratories in the early 1980s estimated a prevalence of NTM infection of 1–2 cases per 100,000 population.[37] A similar survey from 1993 to 1996 reported an annual case rate of 7–8 per 100,000 documenting an increase in isolation of NTM when compared to the previous survey.[38] Because these laboratory-based surveys did not include clinical information, it is likely these types of studies overestimate the prevalence of disease.

The most useful studies combine clinical and microbiologic data to provide estimates of disease rates. The incidence of pulmonary NTM was studied prospectively in France between 2001 and 2003 at 32 sentinel surveillance sites: 262 patients met the ATS criteria for disease (see below).[39] *M. avium* complex was the cause of disease in almost half of the patients followed by *M. xenopi* in 25%, *M. kansasii* in 13%, and rapidly growing mycobacteria in 10%. The overall incidence was estimated to be stable and approximately 0.72–0.74 per 100,000; however, the method for calculating the incidence rate likely underestimated the true incidence.

A recent population-based study from Ontario Province in Canada documented a prevalence of NTM infection of 14.1 per 100,000 in 2003 ($p < 0.0001$).[40] The most common isolate was MAC with a prevalence of 8.4 per 100,000. Thirty-seven percent of 200 patients evaluated at one hospital met ATS criteria for disease.

5.1.1. Risk Factors for Infection and Disease. Skin testing data from Palm Beach, Florida, reported that 32.9% of 447 participants in a population-based random household survey had a positive reaction to *M. avium* sensitin.[41] Independent predictors of a positive reaction included black race, birth outside the United States, and more than 6 years' cumulative exposure to soil. Exposure to water, food, and pets was not associated with skin test reactivity. However, the assessment of water exposure was crude and reactivity to *M. avium* sensitin may be associated with infection but not necessarily disease and thus the risk factors identified in this study may not be relevant to persons with disease.

Male sex, non-Hispanic black race, and birth outside of the United States were reported as risk factors in individuals who underwent skin testing with PPD-B as part of the National Health and Nutrition Examination Surveys (NHANES).[42] As in the previous study from Florida, occupations with the potential for extensive soil exposure, such as in the agricultural or construction industry, were more likely to be sensitized to *M. intracellulare* than persons in other occupations.

Patients who have pulmonary disease caused by NTM often have structural lung disease such as chronic obstructive pulmonary disease,[1,43] cystic fibrosis, bronchiectasis, pneumoconiosis, prior TB, alveolar proteinosis, and chronic aspiration.[44–47] In the study from France noted previously,[39] over 50% of the patients who met ATS disease criteria (except for those with *M. kansasii*) had underlying predisposing factors such as preexisting pulmonary

or immune deficiency. NTM lung disease has been associated with abnormal CF genotypes[48] and α1-antitrypsin phenotypes.[49,50] For example, among 50 patients with bronchiectasis and pulmonary NTM infection, 20% were diagnosed with cystic fibrosis and 50% of the patients had a CFTR mutation identified.[48] Among 98 patients with bronchiectasis in the United Kingdom, 10 had NTM isolated from sputum specimens and cystic fibrosis was more likely in those with NTM than without NTM.[51] In a cohort of 100 patients with rapidly growing mycobacteria, anomalous α-1 antitrypsin proteins were present in 27% of the patients, which is 1.6 times the estimated prevalence in the U.S. population.[52]

Extremely high rates of NTM disease have been reported among miners in South Africa. The incidence of NTM disease in gold miners in South Africa was reported to be 47.6 per 100,000 and that of *M. kansasii*, the most commonly isolated NTM, was 37.0 per 100,000, 34% of whom were HIV infected.[53]

Patients with abnormalities in the IFN-gamma or IL-12 pathways are predisposed to severe mycobacterial infections[54,55] as are patients receiving TNF-antagonist. HIV-infected patients who have advanced disease are at risk of developing disseminated disease. Of note, many women with NTM infection have nodular bronchiectasis and similar body types: scoliosis, pectus excavatum, mitral valve prolapse, and joint hypermobility.[56] The reason for this association has not been definitively determined.

5.2. Epidemic Behavior and Contagiousness

Most infections are believed to arise from environmental exposure to organisms in water, soil, and dust.[57–59] Person-to-person transmission and animal-to-human transmission of NTM are not important factors in acquisition of infection. Thus, community-based outbreaks are unusual although recent outbreaks of mycobacterial furunculosis associated with footbaths at nail salons have highlighted the ubiquitous nature of these organisms.[60–62] Most of the footbath-related infections have been caused by *M. fortuitum* and *M. margeritense*.

There are numerous reports of health-care-associated outbreaks of disease and pseudo-outbreaks.[63,64] Investigations of these outbreaks and pseudo-outbreaks caused by NTM have demonstrated that tap water, ice prepared from tap water, processed tap water used for dialysis, and distilled water used for preparing solutions such as gentian violet are the usual sources for organisms involved.[1]

Most health-care-associated outbreaks and pseudo-outbreaks have involved in rapid growers such as *M. fortuitum* and *M. abscessus*. Infections associated with median sternotomy wounds, injections, plastic surgery, liposuction, LASIK, dialysis-associated outbreaks, long-term central catheters, and middle ear tympanostomy tube replacement have all been associated with infections due to rapid growers.[1]

Slowly growing mycobacteria have also been implicated in several pseudo-outbreaks. For example, 65 *M. simiae* isolates from 62 patients at a community teaching hospital in Houston, Texas, were reported.[65] None of the patients were thought to have clinical evidence of disease and none were treated. The reservoir for this pseudo-outbreak was identified as a contaminated hospital water supply. A similar pseudo-outbreak was described in San Antonio, Texas.[63]

5.3. Geographic Distribution

As noted previously, studies assessing cutaneous sensitization to MAC antigens have demonstrated significant variability in sensitization across the United States. Sixty-five percent of nursing students who came from the southeastern United States had evidence of cutaneous sensitization to *M. intracellulare* antigens compared with only 29% of those from other areas of the country.[35] Skin test surveys of U.S. Navy recruits in the 1960s demonstrated higher rates of reactivity in those from the southeastern United States (56%) than those from the northern states (15–25%), suggesting higher rates of infection.[36] These surveys demonstrated the striking geographic differences in NTM infection.

There is also significant geographic variation in which NTM cause disease. *M. avium* complex has been reported as the most common cause of NTM-related pulmonary disease in almost all studies.[1] However, the next most common NTM that causes disease varies by location. For example, in the United States, *M. kansasii* is the second most common cause of pulmonary disease followed by *M. abscessus*. In Canada, and some parts of Europe, *M. xenopi* is the second most common whereas in northern Europe and Scandinavia, *M. malmoense* is second. In a recent study from France, *M. avium* complex was the most common isolate overall but *M. xenopi* was the most common isolate in Paris.[39]

5.4. Temporal Distribution

For years there has been controversy regarding whether or not the incidence of NTM is increasing. Recent data support the view that the incidence of NTM infections is increasing at least in North America (Figure 1).[40] In a retrospective cohort review from 1997 to 2003 in Ontario, Canada, 222,247 pulmonary isolates from 10,231 patients were identified. The prevalence was 9.1 per 100,000 in 1997 and increased to 14.1 per 100,000 by 2003 ($p < 0.0001$)

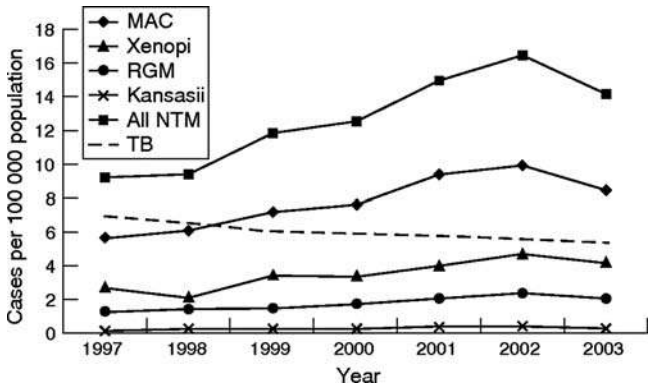

Figure 1. Prevalence of pulmonary nontuberculous mycobacteria (NTM) infections and tuberculosis (TB) case rates in Ontario 1997–2003. All NTM prevalence rates increased significantly (all $p \leq 0.001$). Tuberculosis rates calculated from total number of tuberculosis cases and population data from Statistics Canada (for 1999–2003 from http://www.statcan.ca/english/Pgdb/demo02.htm accessed October 4, 2004) and estimated by back extrapolation (for 1997 and 1998). MAC, *M. avium* complex; RGM, rapidly growing mycobacteria. From Marras et al.,[40] with permission (obtained).

with an average annual increase of 8.4%. Increases were noted among *M. avium* complex, *M. xenopi*, rapidly growing mycobacteria, and *M. kansasii*. Of note, the rate of TB declined 4.0% over the study period. Two hundred patients were evaluated in more detail and 33% fulfilled the clinical, radiological, and bacteriological ATS criteria.

In contrast, in France, a recent report describes the incidence of NTM at being low and stable over a 3-year period.[39] Data from 32 sentinel sites in France described 262 patients who met the 1997 ATS criteria for disease and reported an incidence rate of NTM disease of approximately 0.73 cases per 100,000 inhabitants. Of note, this is an underestimate of the true rate of disease since this was a laboratory-based study and many patients with NTM disease have never been suspected of having NTM disease.

The reasons for the apparent increases in NTM disease are not clear. An aging population, more immunosuppressed patients, waning cross-immunity, improved diagnostics, increased clinical suspicion, and greater environmental exposure may all play a role in the increase in disease. Data supporting the latter come from a recent study that reported on the mycobacterial sensitization to PPD-B in the United States over three decades. Using NHANES, the authors compared the frequency of skin test reactions to *M. intracellulare* antigens during two time periods, 1971–1972 and 1999–2000. Sensitization increased from 11.2 to 16.6% between the two time periods suggesting that exposure to *M. intracellulare* had increased over time. The increase was most notable in foreign-born individuals.

5.5. Age and Sex Distribution

Sensitization to mycobacterial antigens is strongly associated with age. In West Palm Beach, Florida, the prevalence of sensitization peaked in the 41- to 50-year age group[41] whereas in the study reporting sensitization to *M. intracellulare* in the NHANES surveys, the prevalence was highest in the 20- to 39-year age group.[42] In both studies, the prevalence was lower in people older than 60 years.

Age distribution of persons with NTM disease varies by mycobacterial species and site of disease.[66,67] Pulmonary disease is most commonly seen in older patients and patients with MAC lung disease tend to be older than those with *M. kansasii* disease.[68] Patients with lung disease due to rapidly growing mycobacteria are typically at least 60 years of age.[69] In patients with nonpulmonary infections, the age spectrum is greater.

Two studies have reported that sensitization to *M. avium* and *M. intracellulare* antigens is more common among men than women.[41,42] This increase in sensitization is likely related to greater environmental exposure in men than women. Male predominance is marked among persons with pulmonary *M. kansasii* and less so among patients with *M. avium*.[68] However, among older persons with *M. avium* complex pulmonary disease and those with nodular bronchiectatic disease, women predominate.[39] There is a significant female predominance among those with lung disease due to rapidly growing mycobacteria.[69]

6. Mechanisms and Routes of Transmission

6.1. Nontuberculous Mycobacteria in the Environment

The source of NTM infection appears to be through environmental exposure and transmission from human to human has not been described. Molecular epidemiology studies of *M. abscessus* in patients with cystic fibrosis have demonstrated that infections appear to be acquired and not related to person-to-person transmission.[45,70,71] In contrast, genotyping methods have demonstrated similar patterns between isolates cultured from patients and their environments.[72–74] In most cases, the source of infection has been water although soil has also been implicated.[73] A recent study from Japan evaluated the water from the residences of 49 patients with MAC and 43 healthy volunteers. MAC was isolated from 11 samples from multiple bathroom samples but from not other sites in the home. All but one sample came from the patient's homes. In two patients the PFE and RFLP patterns were the same.[75]

NTM have been found in municipal water supplies or treated water supplies from 95 of 115 (83%) dialysis

centers throughout the United States.[76] MAC isolates were recovered from 42 of 108 (32%) of tested locations such as homes, hospitals, commercial buildings, and reservoirs in Los Angles, California.[1] In a study of 50 biofilm samples from a variety of pipe systems in Germany, 90% of the samples contained NTM.[77] At Grady Memorial Hospital in Atlanta, hospital water was felt to be the source of some infections; 25% of patients with MAC disease had the same pulse field pattern as that from hospital water.[78]

7. Pathogenesis and Immunity

The importance of host immunity has been demonstrated in individuals and families with mutations in the IFN-gamma/IL-12 pathway genes[54,55,79] in whom disseminated mycobacterial infections have been reported. In in vitro studies, α-1 antitrypsin synthetic inhibitor of serine proteases, was reported to suppress *M. abscessus* infection in monocyte-derived macrophages by up to 65% ($p < 0.01$), suggesting that α-1 antitrypsin may play a role as an anti-rapid grower host defense factor.[52]

In a study from Japan, 170 patients with MAC lung infection were studied, and of 622 siblings of these patients, 3 had MAC lung disease also.[80,81] The authors concluded that the rate of infection among the siblings was higher than previously estimated among the general population and thus suggested a genetic predisposition to disease. Despite these types of studies, there is little evidence suggesting a host-immune defect in most patients with pulmonary infection.

In patients with HIV infection, disseminated NTM infections typically occur only after the CD4 lymphocyte count falls below 50 cells/μl suggesting that specific T-cell products or activities are required for mycobacterial resistance.[1] MAC presumably enters the body through ingestion of contaminated food or liquid and subsequently spreads through the bloodstream.

There is a striking association between bronchiectasis, nodular pulmonary NTM infections, and a particular body habitus, predominantly in postmenopausal women.[56] It remains to be seen whether or not these women have some sort of subtle immune deficiency that predisposes them to NTM pulmonary infections or whether their predisposition is related to ineffective mucociliary clearance or poor tracheobronchial secretion drainage.

Unlike *M. tuberculosis*, the NTM do not appear to live in a state of dormancy. Moreover, simply isolating NTM from a respiratory specimen does not mean that the patient has NTM-related disease. For years the term "colonization" has been used to differentiate those who have a single or small number of positive cultures over time and in whom progressive disease cannot be demonstrated.[81] At least two observations suggest that colonization is uncommon. First, Prince and colleagues described 21 patients with pulmonary MAC who had no underlying lung disease, most of whom had noncavitary disease that was slowly progressive.[82] Subsequently, Erasmus and colleagues reported the findings on CT demonstrating multiple small nodules and associated cylindrical bronchiectasis in these patients.[83] Taken together, these studies suggested that some patients who were thought to have been colonized did in fact have evidence of disease on CT scans and demonstrated slow clinical and radiographic progression.

8. Patterns of Host Response

8.1. Clinical Features

The most common clinical manifestation of NTM infection is chronic lung disease.[1] However, lymphatic, skin/soft tissue, bone/joint involvement as well as disseminated disease are also important manifestations of infection. The propensity of a specific manifestation varies with the specific species and certain host factors. For example, the rapid growers, while a common cause of lung disease, have a propensity for producing skin and soft tissue infections. HIV-infected patients typically present with disseminated disease whereas persons with cystic fibrosis and elderly white females present with pulmonary disease.

8.1.1. Pulmonary Disease. Chronic pulmonary disease is the most common clinical presentation of NTM disease and usually presents with chronic cough, fatigue, fever, hemoptysis, chest pain, and weight loss. Physical examination may identify certain morphologic characteristics in postmenopausal women and, occasionally men, that include thin body habitus, scoliosis, pectus excavatum, and mitral valve prolapse.

The radiographic features in patients with MAC pulmonary disease are typically divided into primarily nodular bronchiectatic or fibrocavitary disease. In patients with fibrocavitary disease, the radiographic abnormalities consist of upper lobe opacities with evidence of cavitation and volume loss, all suggestive of tuberculosis (Figure 2a, b). Patients with predominantly noncavitary nodular bronchiectatic disease have opacities in the mid and lower lung fields (Figure 3a). High-resolution computed tomography scans demonstrate bronchiectasis often in the middle lobe and lingula with evidence of centrilobular nodules referred to as a "tree-in-bud" pattern (Figure 3b).

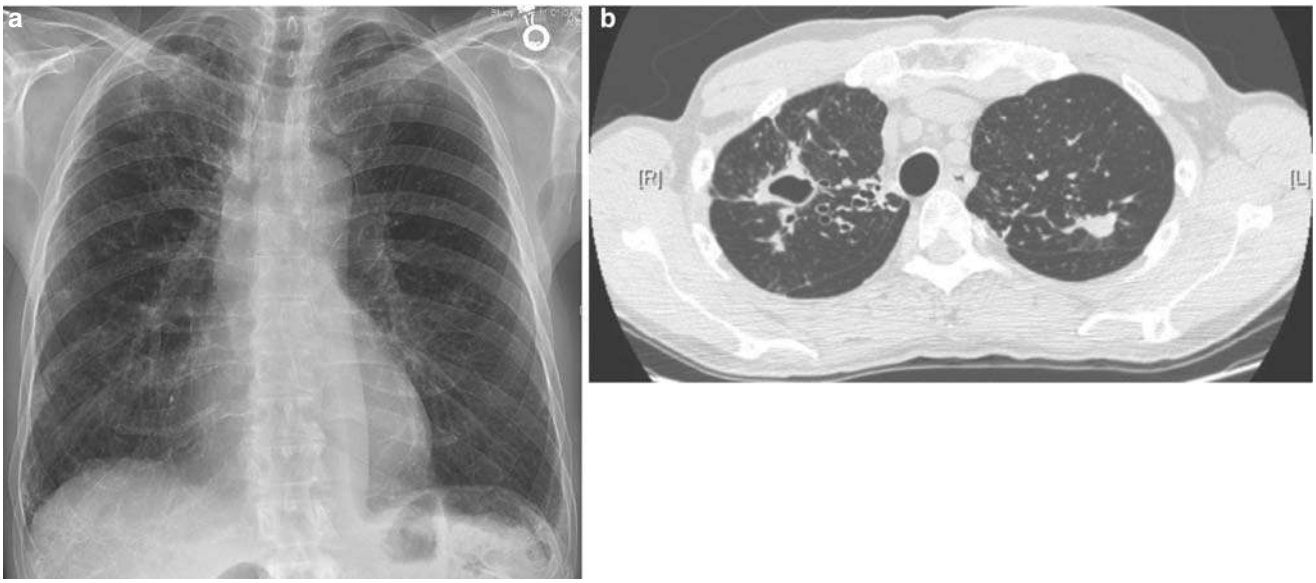

Figure 2. A 76-year-old man with pulmonary *M. intracellulare* disease. (**a**) The chest radiograph demonstrates bilateral upper lobe opacities with a right upper lobe cavity. (**b**) A high-resolution chest computed tomogram demonstrates a right upper lobe cavity with surrounding bronchiectasis and nodules as well as a left upper lobe nodular opacity.

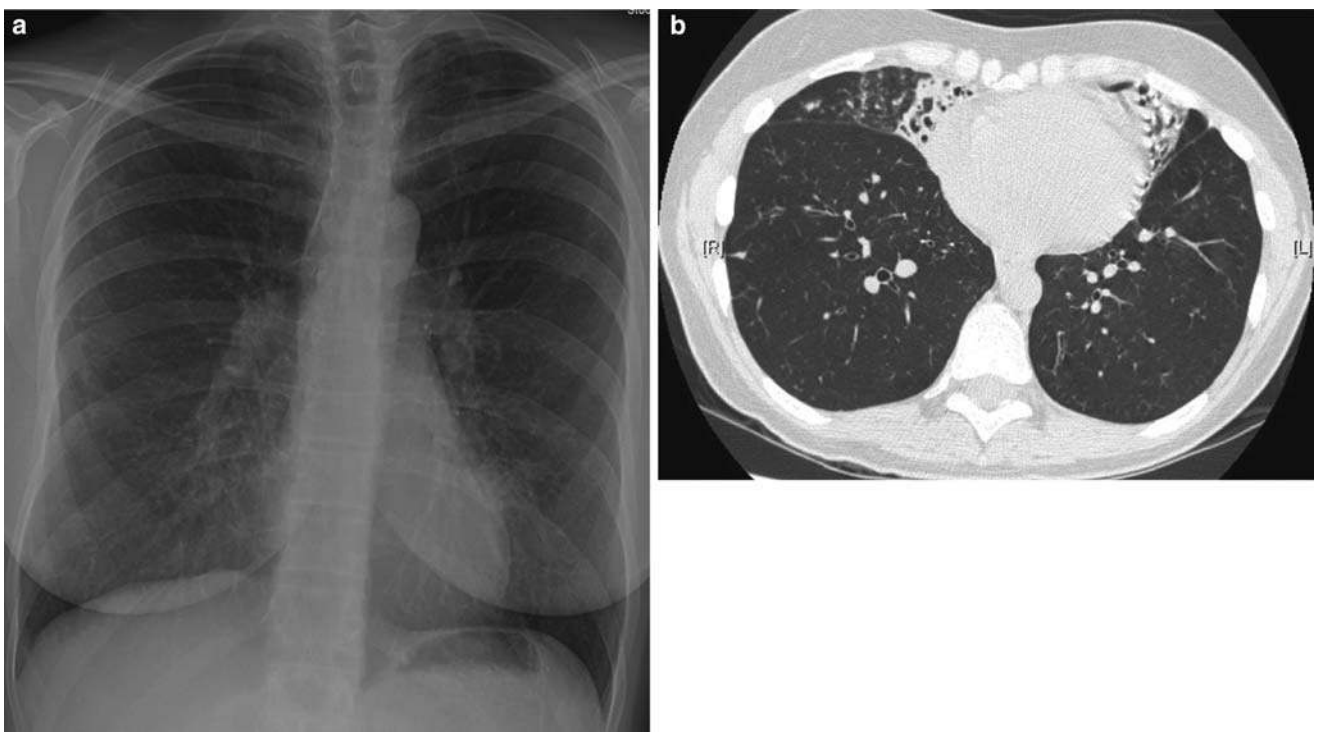

Figure 3. A 50-year-old woman with pulmonary *M. intracellulare* disease. (**a**) The chest radiograph demonstrates right middle lobe and lingula opacities. (**b**) A high-resolution computed tomogram demonstrates right middle lobe and lingular bronchiectasis with some consolidation and centrilobular nodules.

Patients with *M. kansasii* infection usually present with upper lobe cavitary opacities and the cavities are typically thin walled. The chest radiograph in patients with rapidly growing mycobacterial infections usually shows multilobar, patchy, reticulonodular, or mixed interstitial alveolar opacities with an upper lobe predominance. High-resolution CT will show bronchiectasis and small nodules similar to MAC (Figure 4a, b).

M. xenopi is second to MAC as a cause of pulmonary disease in Canada and parts of Europe. Typically, patients with disease due to *M. xenopi* present with underlying chronic obstructive pulmonary disease and the radiographic appearance is similar to that seen in upper lobe cavitary MAC disease.

8.1.2. Lymphadenitis. The most common form of NTM disease in children is cervical lymphadenitis.[1] *M. avium* is the most common etiology accounting for 80% of culture-proven cases. *M. scrofulaceum* is the second most common cause of lymphadenitis in the United States and Australia whereas *M. malmoense and M. haemophilum* are more common in Scandinavia, the United Kingdom, and other areas of northern Europe. *M. tuberculosis* is only isolated in approximately 10% of culture-proven mycobacterial cervical lymphadenitis in the United States but in adults 90% are due to TB.[1]

Infection usually involves the submandibular, submaxillary, cervical, and preauricular lymph nodes in children between 1 and 5 years of age. Involvement of the lymph nodes is usually unilateral and nontender. The lymph nodes may enlarge and eventually rupture producing sinus tracts just like tuberculous lymphadenitis.

8.1.3. Soft Tissue, Skin, and Bone Infection. Although virtually any NTM can cause skin, soft tissue, and bony infection, the most common species to do so are the rapid growers.[84,85] Rapid growers often produce infections at the site of punctures or surgery and present with tender subcutaneous nodules.

8.1.4. Disseminated Infections. Disseminated infections are most commonly associated with advanced HIV infection and other forms of severe immunosuppression. Over 90% of reported disseminated infection in HIV-infected patients are due to MAC and almost all of these are due to *M. avium*.[1] The next most common cause of disseminated NTM disease in HIV patients is *M. kansasii* but a number of other species have also been implicated. Patients present with advanced HIV disease and complain of fever, night sweats, abdominal pain, diarrhea, and weight loss. In non-HIV-infected patients, fever of unknown origin is a common presentation.

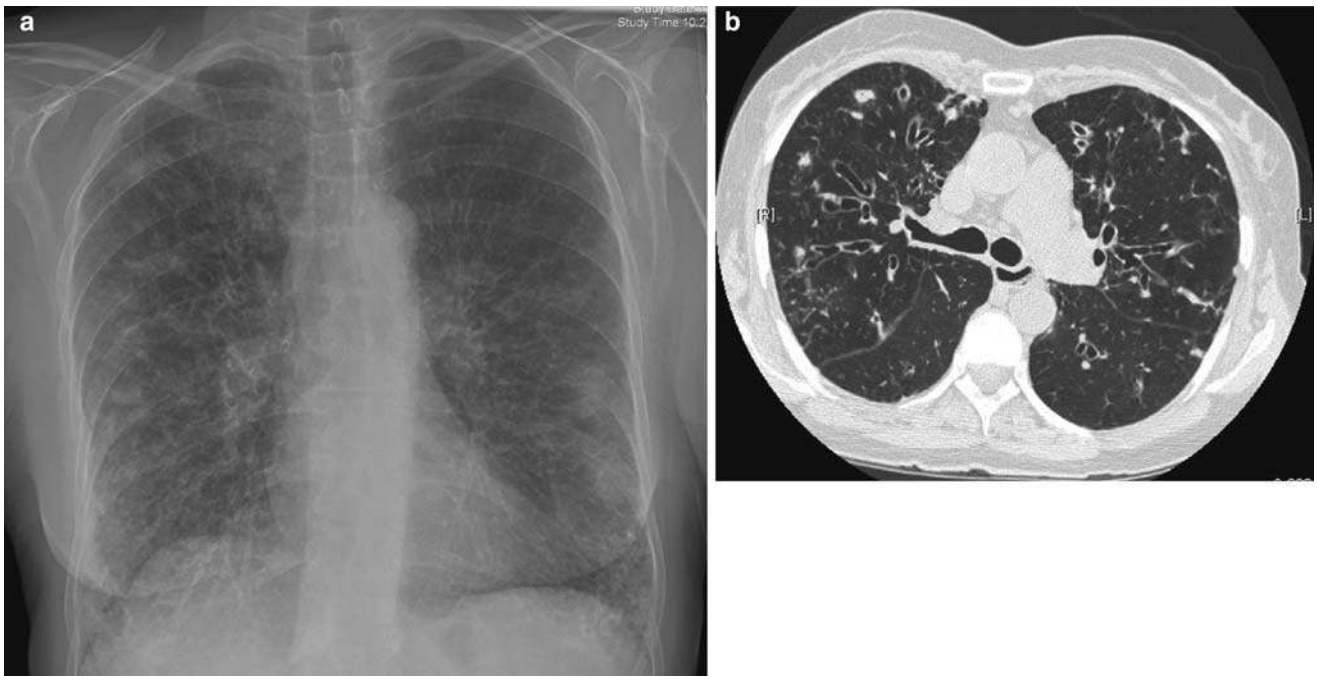

Figure 4. An 84-year-old woman with a history of pulmonary *M. intracellulare* infection who now presents with pulmonary *M. abscessus* infection. (**a**) The chest radiograph demonstrates extensive bronchiectasis with diffuse nodules and airspace opacities. (**b**) A chest computed tomogram demonstrates extensive bronchiectasis with numerous nodules.

8.2. Diagnosis

Finding mycobacteria in a patient's specimen leads to the question of whether the isolate is causing infection/disease in the patient or is simply a contaminate or colonizer. To exclude the transient occurrence of NTM in the patient's respiratory specimen due to exposure to the bacteria, aerosolized from waters or soil, specific criteria have been recommended for the diagnosis of pulmonary disease caused by NTM (see below).[1,86]

8.2.1. Pulmonary Disease. Patients suspected of having a pulmonary NTM infection should be evaluated with a chest radiograph and/or high-resolution computed tomography, particularly when there is no evidence of cavitation on the radiograph. If there is evidence of radiographic abnormalities consistent with an NTM infection, at least three sputum specimens should be obtained for AFB examination and mycobacterial culture. TB as well as other disorders should be excluded.

The clinician must weigh clinical, bacteriologic, and radiographic information in order to diagnose pulmonary NTM infection (Table 2).[1] NTM pulmonary infections should be suspected when a patient presents with a compatible clinical picture and has nodular or cavitary opacities on the chest radiograph or an HRCT scan that shows multifocal bronchiectasis with multiple small nodules. In addition to these clinical criteria, the patient should have at least two positive cultures from separate sputum specimens or a positive culture from at least one bronchial wash or lavage. Ninety-eight percent of patients with two or more positive sputum cultures progressed without treatment in a study published from Japan.[87] Additional diagnostic criteria include transbronchial or other lung biopsy with mycobacterial histopathological features and positive culture for NTM or biopsy showing mycobacterial histopathologic features and one or more sputum or bronchial washings that are culture positive. Some patients who do not meet these criteria at the initial evaluation will do so later so close follow-up is recommended.

8.2.2. Lymphadenitis. Diagnosis is usually made by fine needle aspiration or surgical excision of the involved lymph nodes. However, only 50–82% of excised nodes will be culture positive.[1]

8.2.3. Soft Tissue. The most sensitive way to diagnose infections due to rapid growers is to obtain a tissue biopsy that is cultured and examined histopathologically. Unfortunately, visualization of mycobacteria in the specimen is seen in only about 10% of cases and the yield of culture is not known since most cases that have been reported were culture confirmed.[88,89]

8.2.4. Disseminated Disease. Diagnosis is usually through detection of the causative organism in the blood. In HIV-infected patients *M. avium* can be isolated in over 90% of cases.[1]

9. Control and Prevention of NTM Infections

9.1. General Concepts

There are several differences regarding the treatment of tuberculosis and that of infections caused by NTM. First, not all patients who have an NTM isolated from their sputum specimen require treatment. As noted previously, in some instances, individuals will grow an NTM species from their respiratory specimens but they are both asymptomatic and demonstrate no radiographic progression. Second, unlike with *M. tuberculosis*, in vitro susceptibility results for many NTM do not correlate well with clinical response to antimicrobial therapy; thus clinicians should use such data with a clear understanding of the limitations. Third, while most patients with tuberculosis can be treated with a single four-drug regimen, the many species of NTM dictate

Table 2. Clinical, Radiographic, and Microbiologic Criteria for Diagnosing Nontuberculous Mycobacterial Lung Disease

Clinical	Compatible pulmonary symptoms *and*
Radiographic	Nodular or cavitary opacities on chest radiograph or a high-resolution computed tomography scan that shows multifocal bronchiectasis with multiple small nodules *and* Appropriate exclusion of other diagnoses *and*
Microbiologic	Positive culture results from at least two separate expectorated sputum samples if results are nondiagnostic, consider repeat sputum AFB smears and cultures *or* Positive culture result from at least one bronchial wash or lavage *or* Transbronchial or other lung biopsy with mycobacterial histopathologic features (granulomatous inflammation or AFB) and positive culture for NTM or biopsy showing mycobacterial histopathologic features (granulomatous inflammation or AFB) and one or more sputum or bronchial washings that are culture positive for NTM

Adapted from Griffith et al.[1]

Table 3. Drugs and Dosages Used to Treat Nontuberculous Mycobacterial Infections in Adults

Drug	Daily dose (max)	Three times/week dose (max)
Oral drugs		
Isoniazid	5 mg/kg/day (300 mg)	15 mg/kg/day (900 mg)
Rifampin	10 mg/kg/day (600 mg)	10 mg/kg/day (600 mg)
Rifabutin	5 mg/kg/day (300 mg)	5 mg/kg/day (300 mg)
Ethambutol	15–20 mg/kg/day (1.6 g)	20–35 mg/kg/day (2.5)
Azithromycin	250 mg/day	500–600 mg/day
Clarithromycin	500–1,000 mg/day	1,000 mg/day
Doxycycline	100 mg/day (100 mg)	–
Trimethoprim–sulfamethoxazole	160 mg trimethoprim/800 mg sulfamethoxazole twice daily	–
Ciprofloxacin	500–750 mg twice daily	–
Moxifloxacin	400 mg/day (400 mg)	–
Linezolid	600 mg once or twice daily	–
Parenteral drugs		
Tobramycin	4–7 mg/kg/day IV	–
Streptomycin	10–15 mg/kg/day (1 g) IV or IM	15–20 mg/kg (1.5) IV or IM
Amikacin/kanamycin	10–15 mg/kg/day (1 g) IV or IM	15–20 mg/kg (1.5) IV or IM
Cefoxitin	100–200 mg/kg (12 g/day) in divided doses IV	–
Imipenem	500–1,000 mg 2–3 times/day IV	–
Tigecycline	50 mg twice daily IV	–

IV – intravenously, IM – intramuscularly.

different drugs and regimens (Table 3). Fourth, NTM infections usually require a longer duration of therapy than with tuberculosis, often up to 2 years. And finally, surgical resection/excision is used more frequently in the management of NTM infection than with tuberculosis. As with tuberculosis, NTM should be treated with more than one antimycobacterial drug in order to prevent the emergence of resistance.

The role of in vitro susceptibility testing for managing patients with NTM disease remains controversial. In vitro susceptibility results and clinical outcome do not always correlate and this is particularly true of infections due to *M. avium complex, M. xenopi,* and *M. simiae*.[1] On the other hand, there appears to be better correlation with *M. kansasii* and the rapid growers.

9.2. Chemotherapy

9.2.1. Chemotherapy of Pulmonary Infections.

9.2.1.1. Mycobacterium avium Complex. Prior to the availability of the newer macrolides, the long-term treatment outcomes for patients treated with antituberculosis regimens were approximately 50%.[1] Small, noncomparative studies of azithromycin- and clarithromycin-containing regimens have been associated with higher bacteriologic response rates but long-term follow-up is often unavailable. Treatment responses are also variable with cure rates ranging from 60 to 85%.[90–96]

The ATS currently recommends that the treatment regimen be based on the presence or absence of cavitary disease and whether or not the patient has been treated previously (Table 4).[1] A three-times-a-week regimen is recommended for patients with noncavitary nodular bronchiectasis. A recent study reported that the bacteriologic response to three-times-a-week therapy was poor overall.[95] However, the response rate was better in those with noncavitary disease compared with those who had cavitary disease (71 versus 20%). Factors associated with a good bacteriologic response were having noncavitary disease, being AFB smear negative, no previous treatment for MAC lung disease, older age, and longer duration of ethambutol use. Eight of 139 patients receiving daily ethambutol therapy developed optic neuritis compared with 0 of 90 on intermittent therapy; thus, three-times-a-week dosing may be associated with less optic neuritis than daily dosing.[97]

Daily therapy is recommended for patients with cavitary and/or advanced disease and in those who have been treated previously.[1] An aminoglycoside should be considered in these patients, at least for the first 2–3 months of therapy although a recent study suggested that there was no long-term benefit to this practice.[96] Surgery should be considered in patients who have a macrolide-resistant strain of MAC, have failed treatment, or have primarily focal cavitary disease. Surgery should be performed by a surgical team that is experienced in managing these difficult cases.[98–102]

Table 4. Treatment of Pulmonary Disease Due to *M. avium* Complex Infections

Type of disease	Regimen
Nodular/bronchiectatic disease	Clarithromycin 1,000 mg tiw or azithromycin 500–600 mg tiw and Ethambutol 25 mg/kg tiw and Rifampin 600 mg tiw
Cavitary disease	Clarithromycin 500–1,000 mg/day or azithromycin 250–300 mg/day and Ethambutol 15 mg/kg daily and Rifampin 450–600 mg daily and Streptomycin or amikacin 15 mg/kg tiw
Advance or previously treated	Clarithromycin 500–1,000 mg/day or azithromycin 250–300 mg/day and Ethambutol 15 mg/kg daily and Rifabutin 150–300 mg daily or rifampin 450–600 mg daily and Streptomycin or amikacin 15 mg/kg tiw

Adapted from Griffith et al.[1]
tiw – three times per week.

9.2.1.2. M. kansasii. Patients who are treated with the currently recommended treatment regimen respond well and both treatment failure and relapse are uncommon. Among 180 patients in three studies, the 4-month culture conversion rates were 100% and there was only one long-term relapse.[103–105] Patients with lung disease due to *M. kansasii* should be treated with isoniazid, rifampin, and ethambutol[1] although a regimen including clarithromycin, rifampin, and ethambutol has also been used successfully.[106] As with other pulmonary NTM infections, the treatment duration should include 12 months of negative sputum cultures. For patients whose isolate is resistant to the rifamycins, a three-drug regimen is recommended based on in vitro susceptibility data to clarithromycin or azithromcyin, moxifloxacin, sulfamethoxazole, or streptomycin.[1] Surgical resection is seldom necessary in patients infected with *M. kansasii*.

9.2.1.3. Mycobacterium xenopi. The optimal treatment regimen and duration of therapy for pulmonary disease due to *M. xenopi* are not known, and in vitro susceptibility results may be difficult to interpret because the response of the organism does not always correlate. Patients are usually treated with a typical anti-MAC regimen that includes a newer macrolide, ethambutol, and rifampin, and responses may be enhanced by addition of a newer fluoroquinolone.[1] The mortality rate with *M. xenopi* infection has been reported to be as high as 57%, but this probably reflects the severity of the underlying lung disease.[107]

9.2.1.4. Rapidly Growing Mycobacteria. Treatment outcomes with *M. abscessus* are generally poor, with no antibiotic regimen able to provide long-term sputum conversion in patients with pulmonary disease. *M. abscessus* is susceptible to only a few antimicrobials including the macrolides, imipenem, cefoxitin, amikacin, tigecycline, and occasionally linezolid. Therefore, in vitro susceptibility testing is recommended for selection of a treatment regimen.[1] Current recommendations are to provide periodic drug administration of multidrug therapy including a macrolide, and one or more parenteral agents such as amikacin, cefoxitin, or imipenem for 4–6 months to help control symptoms and prevent progression.[1] Surgical resection should be considered for select patients but only after a period of intensive antimicrobial therapy and only if performed by an experienced surgeon.

M. chelonae is usually susceptible to tobramycin, macrolides, linezolid, imipenem, and amikacin and may demonstrate susceptibility to fluoroquinolones and doxycycline.[1] Isolates are usually resistant to cefoxitin. Treatment should consist of at least two drugs to which there has been demonstrated in vitro drug susceptibility and the duration should be for at least 12 months of culture negativity.

M. fortuitum isolates are usually susceptible to newer macrolides, flouroquinolones, doxycycline, minocycline, sulfonamides, cefoxitin, and imipenem.[1] Therapy should consist of at least two agents with in vitro activity for at least 12 months of culture negativity.

9.2.2. Chemotherapy of Lymphadenitis. Cervical lymphadenitis is usually caused by *M. avium* complex or *M. scrofulaceum* infection.[1] Surgical excision of the involved lymph nodes without chemotherapy is usually curative with success rates of approximately 95%. In patients who fail surgical excision a macrolide-based treatment regimen with or without repeat excision is usually successful.

9.2.3. Chemotherapy of Skin, Soft Tissue, and Bone/Joint Infections. A combination of surgical excision plus multidrug chemotherapy is usually successful for treatment of MAC infections of the skin and soft tissues. The optimal duration of therapy is not known but should probably be 6–12 months in duration.[1] For serious infections caused by rapidly growing mycobacteria, a newer macrolide should be combined with a parenteral medication (amikacin, cefoxitin,

or imipenem) or perhaps another oral agent in the case of infection due to *M. fortuitum*.[1] Therapy should continue for a minimum of 4 months for skin infections and at least 6 months for bone infections. Surgery is generally indicated for extensive disease, and removal of foreign objects such as breast implants, percutaneous catheters, and joint prostheses is necessary.

9.2.4. Chemotherapy for Disseminated Infections. Treatment of disseminated MAC infection in HIV-infected patients should include clarithromycin 500 mg twice daily or azithromycin 500 mg daily, ethambutol 15 mg/kg daily with or without rifabutin 300 mg daily.[1] Treatment should be considered lifelong unless immune restoration is achieved by antiretroviral therapy. MAC treatment can be stopped for patients who are asymptomatic and have achieved a CD4 lymphocyte count of over 100 cells/μl for at least 12 months.[108]

9.3. Prophylaxis of NTM Infections

Prophylactic therapy for NTM is only recommended in the setting of advanced HIV disease. Preventive therapy for disseminated MAC is recommended for HIV-infected patients with fewer than 50 CD4 lymphocytes/μl.[108] Azithromcyin given as 1,200 mg once weekly is the preferred agent but alternative regimens include clarithromcyin 500 mg twice daily or rifabutin 300 mg daily.[109] Primary prophylaxis can be discontinued when patients have responded to antiretroviral therapy with an increase in CD4 cell count to more than 100 cells/μl for more than 3 months.[108,110] Prophylaxis should be reintroduced if the cell count falls to less than 50–100 cells/μl.

As noted previously, NTM infections in health-care settings have been associated with contamination of water sources, biologicals, and multidose vials used in postsurgical infections.[1] In these settings, specific steps can be taken to in order to prevent the use of tap water to wash wounds or equipment and avoidance of multidose vials should be avoided for injections.

Prevention of community-acquired pulmonary infections remains difficult. The organisms have been isolated in tap water and water distribution systems, may tolerate high water temperatures, and are resistant to our typical decontamination methods.[1] Therefore, it is not clear how to best decrease our environmental exposure to these hardy organisms.

9.4. Immunization

No vaccine has been developed for treatment or prevention of NTM infections. However, recent reports suggest that the tuberculosis vaccine Bacille Calmille Guerin (BCG) has some protection against NTM infection. In Sweden, NTM lymphadenitis in children increased after mass BCG vaccination was discontinued in 1975.[111,112] Among the cohorts born in Sweden in the period 1975–1985, the cumulative incidence rate before 5 years of age was estimated at 26.8 per 100,000 in non-BCG-vaccinated children and at 4.6 among those vaccinated.[112] Similarly, in the Czech Republic, *M. avium* lymphadenitis was more common in children who had not received BCG vaccine compared with vaccinated children.[113]

10. Unresolved Problems

The decline of tuberculosis in many countries has been associated with an increase in the number of NTM infections. The reasons for this and just how much NTM disease exists are not known because of the lack of epidemiologic and surveillance data. In order for us to better understand these infections, we need better data on the natural history of NTM infections and how and where individuals become infected. Better diagnostic tests are needed to help us differentiate diseased from non-diseased individuals and we need tests that will correlate with clinical outcomes. Except for pulmonary disease due to *M. kansasii*, the clinical outcomes with most pulmonary NTM infections are suboptimal, so new drugs and better treatment regimens are greatly needed. It is remarkable how little we know about these ubiquitous organisms and the infections they produce. Only better epidemiologic data and clinical trials can answer these many questions.

CHAPTER 42

Tularemia

Paul S. Mead and Jeannine M. Petersen

1. Introduction

Tularemia is an uncommon disease caused by *Francisella tularensis,* a highly infectious gram-negative coccobacillus found in rabbits, hares, rodents, and arthropods throughout the northern hemisphere. Humans become infected through arthropod bites, handling infected animal tissues, ingestion of contaminated food or water, and inhalation of contaminated aerosols. Symptoms vary according to the route of inoculation. The most common clinical syndrome is ulceroglandular tularemia, which is characterized by fever, a skin ulcer at the site of inoculation, and regional lymphadenitis. Other syndromes include glandular, oculoglandular, oropharyngeal, pneumonic, and typhoidal tularemia. Two subspecies, *F. tularensis* ssp. *tularensis* (type A) and *F. tularensis* ssp. *holarctica*(type B), cause the majority of human infections. Because of its ability to cause disease by aerosol, *F. tularensis* has been developed by several countries as a potential bioweapon.

2. Historical Background

Tularemia-like illness (Yato-byo) was recognized as early as 1818 in Japan, where court physician, Homma Soken attributed the illness to the ingestion of hare meat.[1] In 1911, McCoy and Chapin isolated the etiologic agent while looking for plague in California ground squirrels. They named the organism *Bacterium tularense* for Tulare County where the infected squirrel was collected, and they demonstrated passage to rabbits, mice, guinea pigs, and monkeys.[2] Three years later, Wherry, Lamb,[3] and Vail[4] isolated *B. tularense* from the eye of a 28-year-old Ohio butcher with conjunctivitis, fever, and regional lymphadenopathy. The butcher's illness was attributed to handling meat of local wild rabbits, which had been dying mysteriously in large numbers.[5] In 1919, Francis isolated *B. tularense* from the blood of patients with "deer fly fever" in Utah and coined the term "tularemia" to describe the associated illness. In 1924, Ohara independently described a febrile illness associated with butchering hares and replicated the illness by rubbing hearts from ill hares onto the hand of his wife, who had volunteered for the experiment. Two years later, Ohara recognized the similarities between this illness and tularemia and sent specimens to Francis who confirmed it as due to *B. tularense.*[6] Between 1928 and 1935, cases of tularemia began to be reported in Russia, Norway, Canada, Sweden, and Austria.[7–9]

In 1959, the organism was placed in it own genus, *Francisella*, based on morphology, culture, biochemical, and pathogenic properties.[10] That same year, Olsufiev concluded that there were two distinct types of tularemia, with differences in virulence, geographic distribution, animal reservoirs, and culture characteristics of the causative organisms.[11–13] The names *Francisella tularensis tularensis* and *Francisella tularensis palaearctica* (*holarctica*) were proposed for these two subspecies.[10]

As understanding of the ability of *F. tularensis* to cause epidemics, epizootics, and laboratory infection increased, the potential of *F. tularensis* as a bioweapon was explored. Experiments with human volunteers in 1961 confirmed the potential for intentional airborne transmission.[14] Tularemia was subsequently developed as a biological weapon by the Soviet Union, the United States, and possibly other countries.[13] In more recent years, concern about bioterrorism has lead to renewed research in tularemia.[15]

3. Methodology

Current understanding of tularemia is based on case reports, outbreak investigations, routine surveillance, ecological studies, and laboratory experiments conducted on both animals and humans. Recent advances in molecular techniques have yielded improved diagnostic tests and a better understanding of the organism's genetic diversity and pathogenic properties.

3.1. Sources of Data

Global statistics on tularemia incidence in humans are not available. In the United States, tularemia has been a reportable condition since 1927, with a brief hiatus from 1995 to 1997.[16] State and local health departments report cases electronically to the Centers for Disease Control and Prevention (CDC), which publishes provisional and final tallies in the *Morbidity and Mortality Weekly Report* (MMWR). Surveillance summaries for various time periods are also available for Sweden,[17] Japan,[18] Slovakia,[19] and Turkey.[20] Under-reporting is likely given the bacterium's fastidious nature and the self-limiting course of many infections.

3.2. Surveys

Past infection with *F. tularensis* can be measured by serology or a skin test,[21] which though sensitive is no longer available. Surveys for human infection have generally focused on populations thought to be at greater than average risk, including Native Alaskans,[22] animal trappers,[23–25] farmers,[26,27] workers in sugar beet factories,[28] and landscapers.[29] Although not representative of the general population, these surveys have demonstrated high rates of seropositivity in some populations and the potential for mild and asymptomatic infection.

4. Biological Characteristics

4.1. Bacteriology

F. tularensis is a small (0.2×0.2–$0.7\ \mu m$), weakly staining, gram-negative, pleomorphic coccobacillus. Members of the *Francisella* genus are characterized by a unique fatty acid content and are not phylogenetically related to any known human pathogen. *Francisella* are strictly aerobic and non-spore forming.[30]

On the basis of DNA hybridization, three species have been identified within the genus *Francisella*, *F. tularensis, F. novicida*, and *F. philomiragia*. *F. philomiragia* is a rare cause of illness among immune compromised persons and victims of near-drowning.[31–33] It can be distinguished from *F. tularensis* by biochemical reactions, most practically a positive oxidase reaction. First discovered near the Great Salt Lake in Utah, *F. philomiragia* is capable of growing in nutrient broth containing 6% NaCl and is often associated with brackish habitats. In spite of these phenotypic differences, the two species show >98.3% similarity by 16S rRNA sequencing.[30]

F. novicida is a similarly rare cause of human illness, seen primarily in immunocompromised patients; it has not been associated with any animal species or arthropod vectors.[33,34] Also isolated from the Great Salt Lake in Utah, *F. novicida* is capable of growing in nutrient broth containing 6% NaCl. A wound infection with *F. novicida* in an Australian fish farmer represents the sole human *Francisella* isolate from the southern hemisphere.[34] *F. novicida* shows >99.8 similarity to *F. tularensis* by 16S rRNA sequence comparison and has been proposed reassignment as a subspecies of *F. tularensis*.[35]

Within the species *F. tularensis*, three subspecies are currently recognized: ssp. *tularensis* (type A), ssp. *holarctica* (type B), and ssp. *mediasiatica*. The subspecies share >99.8% similarity by 16S rRNA sequencing.[36] Subspecies *tularensis* (type A) and subspecies *holoarctica* (type B) account for nearly all human infections. With the exception of a recent collection of isolates recovered near Bratislava in Slovakia,[37] type A strains are found only in North America. Type B strains are found throughout the northern hemisphere in Europe, Asia and North America. Type A strains have been considered more virulent than type B strains; however, recent studies suggest that the reverse may be true for type A strains from the western United States.[38] Subspecies *mediasiatica* has been isolated from animals in central Asia but has not been reported as a cause of human illness. Virulence on *Ft mediasiatica*, based on animal studies, is thought to be moderate.

Recent studies suggest that additional, unnamed species likely exist in the environment. For example, PCR amplification of DNA extracts from soil and water samples from the Houston area found evidence of a wide variety of *Francisella*-related organisms, including sequences that were 99.9% similar to previously reported sequences from *F. novicida* isolates.[35]

4.2. Ecology

The ecology of *F. tularensis* is complex and poorly understood. In nature, *F. tularensis* subspecies type A and type B are thought to be maintained in distinct, but incompletely defined cycles, with type A occurring in ter-

restrial environments and type B associated more often with aquatic environments. In the terrestrial cycle, rabbits and hares typically serve as amplifying hosts and ticks or biting flies as arthropod vectors. In the aquatic cycle, beaver, muskrat, and voles serve as important mammalian hosts and appear to shed live organisms into their environments. Recent studies have shown that type B *F. tularensis* can also infect free living amoeba in a manner reminiscent of *Legionella*, suggesting a role for amoeba as a natural reservoir[39] and potentially explaining the association with aquatic environments.[40]

F. tularensis can infect over 100 animal species, although not all become ill.[41] The organism has been recovered from a wide variety of vertebrates, including domestic mammals (cats, sheep), birds (grouse, pheasants, quail, mallards), reptiles, amphibians, and fish. The animals considered most important in enzootic cycles are rabbits, hares, and rodents, especially voles, muskrats, and beavers. The importance of any particular species as a reservoir or source of infection may vary depending on geographic location and local ecological factors. In North America, cottontail rabbits (*Sylvilagus*) and jackrabbits (*Lepus* spp.) are both highly susceptible to disease and linked to human infection. In Europe, hares (*Lepus* spp.) and voles (*Arvicola terrestris*) are highly susceptible to disease and linked to human infection.

A number of different arthropods have also been found to be infected with *F. tularensis*. Ticks are believed to play an important role both as vectors transmitting *F. tularensis* to vertebrates[7] and as reservoirs that maintain the organism over time through transstadial passage.[41,42] Early investigators also reported transovarian transmission; however, this has not been confirmed in later studies.[42] In North America, natural infection has been described in at least 13 species of ticks belonging to four genera, *Dermacentor*, *Ixodes*, *Amblyomma,* and *Haemaphysalis*.Transmission of tularemia to humans has been associated in particular with the *D. andersoni* (the wood tick), *D. variabilis* (the American dog tick), *D. occidentalis* (the pacific coast dog tick), and *Amblyomma americanum* (the lonestar tick). The rabbit tick, *Haemaphysalis leporis-palustris*, is thought to play a key role in maintaining the enzootic cycles in rabbits and may serve as a bridging vector for transmission to birds such as grouse, on which they also feed.[42] In Eurasia, *F. tularensis* has been isolated from *I. ricinus, D. reticulatus*, *D. marginatus*, *H. concinna, Rhipicephalus rossicus*, and a variety of other species in these genera.[12,19,12,43,44] Although *Ornithodorus* ticks may be capable of transmitting *F. tularensis* experimentally, there is no evidence that argasid ticks are important vectors in nature.[41]

Tabanid flies, including *Chrysops discalis*and *C. fulvaster*, have been found naturally infected in North America and Eurasia. These biting flies are mechanical vectors that can transmit infection to a wide a range of hosts, including humans. *F. tularensis* has reportedly been isolated from various species of mosquitoes in Scandinavia and Russia, with mechanical transmission to humans reported. Natural infection of mites and fleas has been reported, but these taxa are generally considered of minor importance in disease maintenance or transmission.[42]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

Over the last century, tularemia has become a rare disease in the United States. Reported cases have declined from over 1,600 cases in 1940 to 154 cases in 2005 (Figure 1), yielding a current national incidence of 0.05 cases per 100,000 population per year. This decrease has been attributed to a marked decline in rabbit hunting as a source of sustenance and entertainment.[41] Although tularemia has been reported from all states except Hawaii, just four states accounted for 56% of all cases reported in the United States from 1990 to 2000.[45] Population-based incidence rates for Europe and Asia are not readily available and may not be particularly informative given the wide annual variation in reported cases in some regions.

5.2. Epidemic Behavior

Epidemics and outbreaks of human tularemia usually occur in association with animal epizootics, although these may not be recognized without a careful environmental investigation. In Sweden, quiescent periods with few or no reported cases are punctuated by epidemic years with hundreds or even thousands of human cases.[17,46,17,47] In contrast, the number of reported cases is reasonably consistent from year to year in the United States, although local outbreaks and clusters do occur. Epidemics among humans may also be triggered by war and social disruption.[47] Large outbreaks were observed in eastern Europe and the Soviet Union during World War II,[12] in Japan during postwar reconstruction,[48] and more recently in Kosovo following several years of civil unrest.[49]

As with other diseases, the study of tularemia outbreaks has done much to illuminate sources and mechanisms of transmission. Following on the work of Francis, deer flies (*C. discalis*) have been implicated in several outbreaks of human tularemia, all in the western United States.[50–52] In a 1973 outbreak in Utah, 73% of 38 patients reported a definite or likely deer fly bite.[51] A field investigation confirmed

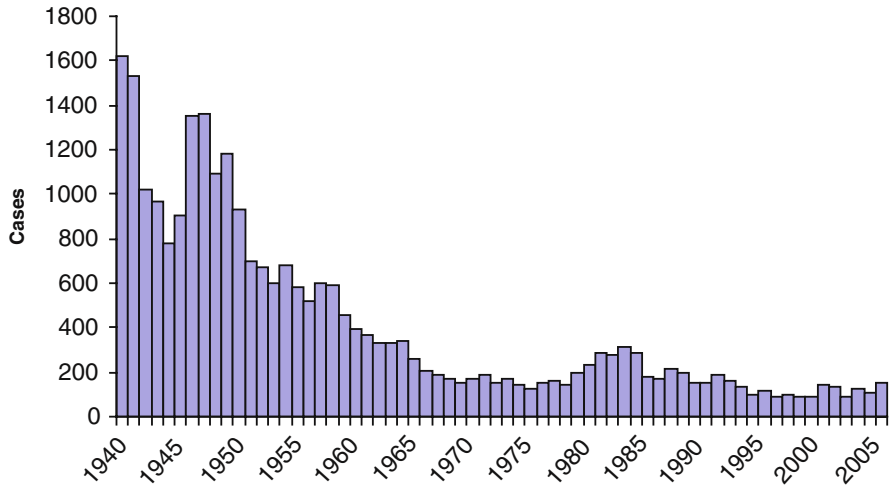

Figure 1. Reported tularemia cases, United States, 1940–2005.

the presence of an epizootic among rabbits, and *F. tularensis* was recovered from pooled collections of deer flies, tissues of jackrabbits and cottontail rabbits, and from rabbit ticks, *H. leporis-palustris*.

The first recognized tick-associated outbreak occurred in 1946 among soldiers on maneuvers in Tennessee.[53] Thirty-two of 50 infected soldiers reported a tick bite before illness onset. One patient died, and others had illness lasting as long as 6 months. Although the vector species could not be determined with certainty, all ticks collected in the area were *A. americanum*, an aggressive human-biting species. The dog tick, *D. variabilis,* has been implicated in outbreaks on Indian reservations in South Dakota[54,55] and Montana.[56] Interestingly, *D. variabilis* ticks collected from area dogs yielded both type A and type B *F. tularensis.*[54] In all three outbreaks, cases occurred primarily among Indian children and were associated with tick bites on the head or neck. Illness was relatively mild and characterized by cervical or occipital lymphadenopathy. The wood tick*, D. andersoni,* has been shown to transmit tularemia among rabbits,[57] but has not been linked to recognized outbreaks among humans. Mosquitoes have been implicated epidemiologically in summertime outbreaks in Scandinavia, but not in North America.[46] In a Swedish case–control study with 270 cases and 438 controls, mosquito bites were identified as the main risk factor, with an odds ratio of 8.8.[58]

Although animal contact usually occurs on an individual basis and produces sporadic infections, outbreaks due to animal exposure have been documented among specific populations. In the spring of 1968 in Addison County, Vermont, 47 cases of tularemia were diagnosed during a 4-week period among persons who had trapped or handled and skinned muskrats, including 87% of those trapping along a particular creek.[59] Thirty-nine of the cases were symptomatic and eight were asymptomatic seroconversions. No deaths were reported; however seven patients had chronic or reoccurring symptoms lasting several months. Wearing gloves while skinning the animals (or having someone else skin the animals) appeared to be protective. *F. tularensis* was isolated from muskrats, mud, and water collected from the stream. No ticks or fleas were recovered from 18 muskrats captured along the stream, supporting the notion that transmission among the muskrats occurred directly through ingestion of contaminated water or food. During the same year, muskrat-associated epizootics were reported in New York and Ontario.[59] Although less common, outbreaks have also been associated with trapping of aquatic invertebrates. In 1998, an outbreak of ulceroglandular tularemia caused by type B *F. tularensis* was reported in Spain among persons collecting freshwater crayfish.[60]

Waterborne transmission to humans was first described in the former Soviet Union, with outbreaks linked to both natural bodies of water and water from wells and municipal systems.[61] In 1936, Karpoff and Antonoff reported an outbreak among 43 field workers who developed tularemia, primarily oropharyngeal, after drinking from a stream while mowing hay.[9] Co-workers who drank from a neighboring stream remained well, and *F. tularensis* was later isolated from the implicated stream. A second outbreak occurred in a railway station and was linked to unchlorinated water piped from a stream, while another was attributed to water from a well which, on inspection, contained rodent carcasses. Unchlorinated water from municipal aqueducts has also been implicated as the source of outbreaks in Italy[62,63] and in

Turkey.[20] A seasonal association with respect to waterborne outbreak has been noted, with those occurring during the summer more often associated with natural bodies of water, whereas those occurring in the fall and winter months are more often associated with wells and piped water.[61]

Outbreaks due to aerosol exposure have occurred in several different settings. In 1959, hundreds of cases of pneumonic tularemia were documented among Austrian sugar factory workers.[28] The workers likely became ill through inhalation of aerosols generated during the mechanical washing and chopping of sugar beets, which that year were contaminated with the bodies of many dead field voles. In the winter of 1966, over 600 cases were reported in Sweden, primarily among farmers.[27] This epidemic was preceded by a large increase and sudden die-off in local vole populations. Hay stores of area farms were heavily contaminated with dead voles and their feces, and the dust generated by farmers while trying to clear these contaminants was considered the likely mode of transmission. Although some patients reported skin ulcers consistent with ulceroglandular tularemia, 32% reported sore throat, 26% conjunctivitis, and 11% symptoms of pneumonia. Overall, 83% reported contact with hay contaminated by voles. *F. tularensis* was recovered from voles, vole feces, and contaminated hay. Serologic studies revealed that over 20% of the population had been infected in some areas, with approximately a quarter of these infections being subclinical. In 1982 a similar outbreak of hay-associated pneumonic tularemia occurred among farmers in northern Finland.[64]

In North America, outbreaks of pneumonic tularemia have been described on Martha's Vineyard, an island off the southern coast of Massachusetts. Seven people developed pneumonic tularemia after staying together in a single cottage on the island in 1978.[65] Although the source of the outbreak could not be proven, the patients may have been infected when a pet dog, just back from catching rabbits in the rain, shook inside the cottage. More recently, an outbreak with 15 cases of pneumonic tularemia, including one fatality, was reported.[66] Type A *F. tularensis* was isolated from the fatal case. Patients were significantly more likely than controls to have mowed lawns or cut brush in the 2 weeks before their illness, but only one patient reported a known rabbit exposure. A serosurvey of island landscapers showed that 9% had evidence of past infection with *F. tularensis.* Elevated antibody titers were associated with mowing and leaf-blowing activities.[29] Smaller clusters of airborne transmission associated with mowing over sick or dead rabbits have been reported.[67]

Although *F. tularensis* can be transmitted through ingestion of contaminated foods, large outbreaks linked to commercial foodstuffs have not been reported. In the Czech Republic, 131 nursing home residents developed oropharyngeal tularemia after drinking juice made from fallen apples contaminated by rodents.[68] Smaller clusters include five cases attributed to eating strawberries,[69] and two cases of oropharyngeal tularemia in a couple who shared a meal of medium-cooked rabbit at a Berlin restaurant.[70]

5.3. Geographic Distribution

Tularemia occurs in regions throughout the northern hemisphere. In Europe and Asia, tularemia has been reported in Scandinavia, continental Europe, central Asia, Middle East, Russia, northern regions of China, and Japan, but not north of the arctic or in the British Isles.[42] In North America, *F. tularensis* has been found from northern Mexico to the arctic circle in Alaska.[42] This global distribution correlates with the holoarctic faunal zone and presumably relates to the distribution of vertebrate and arthropod species important for maintenance and transmission of the organism. In the United States, tularemia is reported most commonly in the south central states (Figure 2).

5.4. Seasonal Distribution

The seasonal distribution of human tularemia varies with the prevailing source of infection and can change over time with changes in human behavior. Studies from the United States typically reveal a bimodal distribution with winter and summer peaks due to infections acquired from rabbits and ticks, respectively.[68,71–73] Before 1950, the majority of cases occurred in winter. However, as rabbit hunting waned in the United States as a source of food and recreation, the total number of cases declined and the seasonality shifted toward that of a summertime disease.[74] Currently 70% of cases occur from May through August.[45] In Japan where exposure to hares remains the leading source of infection, the majority of cases continue to occur in the winter months.[48,75] In Scandinavia, most cases occur during the months of July through September with mosquitoes implicated in disease transmission.[27,76] Conversely, in a 40-year series from the Czech Republic, the majority of cases occurred from November through February, and contact with hares, rodents, or other mammals was reported as the likely source of infection.[68]

5.5. Age and Sex Distribution

The demographics of tularemia vary slightly from region to region reflecting differences in prevailing modes of transmission. Males account for the majority of cases in series from the United States,[45] Japan,[48] Finland,[76]

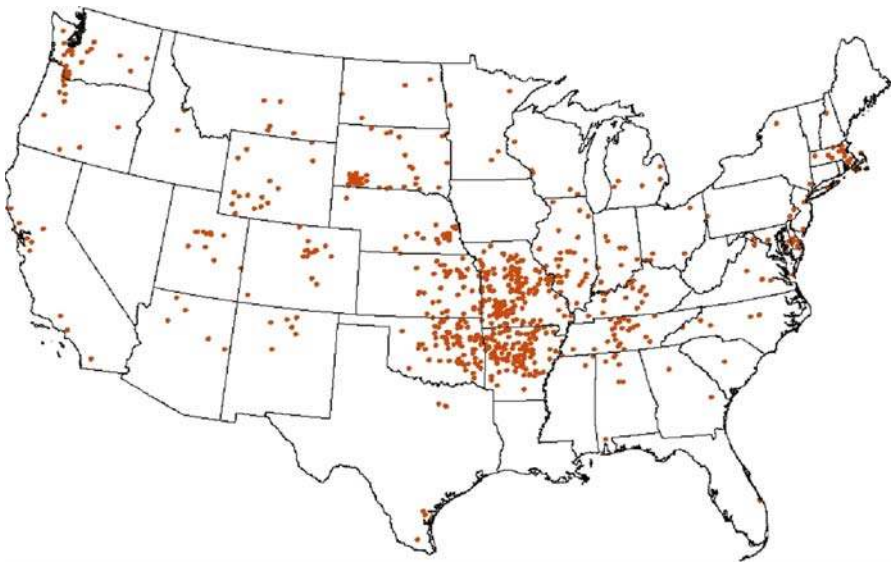

Figure 2. Reported cases of tularemia in humans, United States, 2000–2005.
1 dot placed randomly within country of residence for each reported case

and Sweden.[17] This higher incidence has been attributed to greater exposure through occupation or recreational activities (e.g., hunting).[58] Conversely, in a series from Turkey where waterborne cases of oropharyngeal tularemia predominate, 64% of identified cases were in females.[20] The age distribution of reported cases in the United States is bimodal, with highest rates among children aged 5–9 years and adults aged 55 and older.

5.6. Occupation and Recreation

As with many other zoonotic diseases, the risk of tularemia is closely linked to occupation and recreational activities. Hunters, trappers, sheep shearers, veterinarians, forest rangers, game wardens, hikers, campers, and others with frequent animal or arthropod exposure are at increased risk of infection. In a survey of Native Alaskan men, as many as 62% had positive skin tests for tularemia.[22] In some areas, farmers and landscapers appear to be at increased risk of pneumonic tularemia as a consequence of exposure to contaminated dust and aerosols.[27,64,27,66] *F. tularensis* is highly infectious when grown in culture, and numerous cases have been documented among laboratory workers.[77,78] Recently, a few cases have been linked to commercially traded pets, suggesting that persons in the pet industry may also be at increased risk.[79,80]

5.7. Other Factors

In the United States, the incidence of tularemia is approximately 10-fold higher among American Indians and Alaskan Natives as compared with whites. This difference is attributed to greater exposure to infected animals and arthropods among these ethnic groups.[45]

5.8. Occurrence in Different Settings

Although tularemia infections are generally more common in rural areas in association with outdoor activities that promote direct contact with infected animals or arthropods, cases occasionally occur in urban and other atypical settings. Five children living in urban Baltimore developed pneumonic tularemia after contact with their dog, which had caught and killed a rabbit in a nearby park.[81] Sporadic cases have also been reported among children living in inner cities.[82,83] Although rarely associated with human illness, several outbreaks in urban zoos, primarily among primates, have been reported.[84,85]

6. Transmission to Humans

Humans are highly susceptible to infection with *F. tularensis*. The average infectious dose for humans is estimated at 10 organisms by subcutaneous inoculation and 25 organisms by aerosol;[14,86] animal studies suggest that the infectious dose is orders of magnitude higher when the organism is ingested or applied to intact skin.[87–89] Person-to-person transmission of *F. tularensis* has not been demonstrated, and no special precautions are needed for managing infected patients.

Most human infections occur through cutaneous exposures. Biting flies act as mechanical vectors introducing the organism directly into the skin. During tick bite, *F. tularensis* may be inoculated directly with saliva or indirectly from tick feces. Hands may become contaminated when skinning or butchering an infected animal, tissues of which can contain up to 10^7/organisms per gram. The organism may then enter through small cuts in the skin or be transferred to the eye or other mucus membranes. Humans may also become infected through bites of infected mammals, especially cats,[90] or exposure to dogs that have caught a sick or dying rabbit.

Infection of the oropharynx is associated with ingestion of contaminated water or food, with few or no signs of gastrointestinal disease.[91] Inhalational exposures can occur during agricultural activities that may expose the individual to rodent contaminated dust. In Scandinavian outbreaks, manipulation of hay appears to be a common exposure,[64,92] and experimental studies have shown that *F. tularensis* can survive in hay for months when held at cold temperatures.[93] Aerosols may also be generated when animals are skinned or butchered. Perhaps the most extreme expression of this occurs when a sick or dead animal is accidentally or intentionally run over with a power mower, a practice that has given rise to the term "lawnmower tularemia."[67] In laboratory studies, the ability of aerosols to infect primates decreases rapidly over a few hours, even though viability of the organisms persists.[94] Whereas large particles may become trapped in the oropharynx,[95] particles 8 μm or smaller reliably cause pneumonia in nonhuman primates.[96,97]

7. Pathogenesis and Immunity

7.1. Pathogenesis

Within the vertebrate host, *F. tularensis* is considered an obligate intracellular pathogen[98] that replicates within macrophages, hepatocytes, and other cells.[99] Once introduced into the skin or mucus membranes, the bacteria multiply locally, producing an ulcerating lesion and spreading to the local lymph nodes. Infection causes follicular hyperplasia in lymph nodes which progresses rapidly to focal suppurative necrosis and ultimately granuloma formation. A bacteremic phase follows, resulting in seeding of other organs, especially liver, spleen, lung, and bone marrow. Following inhalational exposure a comparable process occurs, with destruction of bronchial tissues corresponding to skin ulceration and hilar enlargement corresponding to regional lymphadenitis.[92] Histologically, tularemia is characterized by granulomatous lesions with areas of focal caseous necrosis.[100] In autopsy series, caseating granulomas, grossly indistinguishable from those caused by tuberculosis, have been found in the lungs, spleen, lymph nodes, and bone marrow.[99]

Virulence factors for *F. tularensis* are largely unknown. The lipopolysaccharide (LPS) lacks classic biologic activity of endotoxin in stimulating cytokine production.[101] A capsule encases the bacterium and helps protect against complement-mediated killing in the serum; however, it is not necessary for survival following phagocytosis.[102] *F. tularensis* enters macrophages without triggering a respiratory burst, an ability that appears related to the activity of AcpA, a protein with acid phosphatase activity. Within the macrophage, *F. tularensis* multiplies within the phagosome. The phagosome does not fuse with lysosomes but does acidify, thus producing an environment essential for the growth and acquisition of iron by the organism. No secreted toxins have been identified.[101]

7.2. Immunity

LPS in the capsule and other proteins of *F. tularensis* elicit a humoral response that can be used diagnostically to demonstrate infection. Antibody titers peak approximately 6 weeks after illness onset and may remain elevated for several years. As expected for an intracellular pathogen, antibody appears to play only a minor role in resistance to infection relative to cell-mediated immunity.[99] In animal models, passive transfer of mononuclear leukocytes or T lymphocytes from immunized animals protected against challenge with virulent strains, whereas immune serum did not. In animal models, protection against virulent strains requires CD4+ and CD8+ T-cell responses, although recent work suggests that other populations may also have a role.[103] Studies using B-cell knockout mice confirm that animals are only marginally compromised in controlling primary sublethal infection and suggest another role for B cells in secondary immunity independent of antibody production.[104] Once induced, cell-mediated immune responses persist for long periods. In a follow-up study of naturally infected patients, T-cell response to *F. tularensis* remained vigorous 25 years later.[105] Although re-infection has been documented, it is extremely rare.[99]

8. Patterns of Host Response

In humans the clinical manifestations of *F. tularensis* infection range from subclinical to life-threatening. The clinical presentation is determined by the route of exposure, the dose, and the infecting strain. The average incubation

period is 3–6 days, but ranges from 1 to more than 14 days. For those who become ill, clinical course and outcome are strongly influenced by host characteristics and the timeliness and appropriateness of medical care.[106]

8.1. Clinical Features

Six primary clinical syndromes have been described: ulceroglandular, glandular, oculoglandular, orophoryngeal, pneumonic, and typhoidal tularemia. All forms are characterized by sudden onset of fever, chills, headache, malaise, fatigue, myalgias, and arthralgias. Fever can be high[104] with a paradoxically slow pulse. Skin manifestations have been reported in 8–40% of patients and include vesiculopapular eruptions, erythema nodosum, and erythema multiforme.[107–113] White blood cells counts may or may not be elevated.[112,114]

Ulceroglandular tularemia is the most commonly reported clinical syndrome in most areas and results from cutaneous exposure through arthropod bites or direct contact with tissues or secretions of an infected animal.[107,115,107,116] A small papule appears concurrent with the onset of fever. Over the next few days, regional adenopathy develops and the skin lesion evolves into an ulcer (Figure 3). Usually solitary, the ulcer may develop satellite papules and pustules. The regional lymph nodes become tender and enlarged with erythema of the overlying skin. Suppuration was common prior to the availability of antimicrobial treatment. A small proportion of patients develop secondary pneumonia, although this is generally mild.[112] During the latter stages of infection, the spleen may be enlarged. The differential diagnosis for ulceroglandular tularemia includes bubonic plague, sporotrichosis, *Mycobacterium marinum* infection, chancroid, tick typhus, anthrax, and staphylococcal lymphadenitis. Glandular tularemia is similar to ulceroglandular disease, but without an obvious cutaneous ulcer. In addition to the diseases mentioned above, glandular tularemia may be confused with cat-scratch disease, tuberculosis, toxoplasmosis, and lymphogranuloma venereum.

Figure 3. Ulcer on thumb of a patient with ulceroglandular tularemia.

Oculoglandular tularemia is believed to result from direct inoculation of organism into the eye, either from contaminated fingers or possibly through aerosols.[4,72,4,117,118] Historically, this has been associated with skinning and butchering rabbits.[4,119] Currently, oculoglandular tularemia accounts for fewer than 5% of reported cases.[107,115,107,116] The patient usually presents with fever, unilateral conjunctivitis with purulent discharge, swelling of the eyelids, and necrotic yellow ulcers or pustules on the palpebral conjunctivae. Adjacent lymph nodes, including preauricular, submandibular, and cervical, may be tender and enlarged. In the original case report by Vail, a pustular eruption was noted on the skin adjacent to the eye.[4] Corneal edema and glaucoma have been reported as complications.[120]

Oropharyngeal tularemia is associated with ingestion of contaminated water or food.[69] Occasionally, it may occur after an inhalational exposure. Patients complain of sore throat and neck swelling. Physical examination reveals pharyngitis which may be exudative or accompanied by small ulcers. There is marked cervical adenopathy, but it may be unilateral. Without effective treatment, suppuration is common.[20] Differential diagnoses include viral and streptococcal pharyngitis, diphtheria, mumps, and the conditions mentioned above that may mimic cervical glandular tularemia.

Pneumonic tularemia can be either primary, following inhalation of the organism, or secondary, following hematogenous spread to the lungs from other areas of the body.[121] Many reported series include both,[122,123] obscureing potential differences in their clinical features. Regardless, the presentation is not readily distinguished from other forms of community-acquired pneumonia, underscoring the importance of a careful exposure to history. Symptoms include fever, headache, dry paroxysmal cough, pleuritic or retrosternal pain, and dyspnea. A wide variety of radiographic findings have been described, including lobar and multilobar infiltrates, lung abscess, and hilar adenopathy.[112,115,112,122,124] Pleural effusions have been reported in 20–30% of cases, and by most reports appear to be transudative.[112,122,112,123] The differential diagnosis includes community-acquired pneumonias caused by *Mycoplasma*, *Chlamydia*, *Legionella*, *Histoplasma*, and common bacterial and viral agents. Additional etiologies to consider are Q-fever, inhalational anthrax, pneumonic plague, and tuberculosis. Because pneumonic tularemia can be

severe, it should be considered in the differential diagnosis of any patient with community-acquired pneumonia.

The term typhoidal tularemia is found throughout the literature and was originally used to designate patients with systemic infection but no skin lesions, lymphadenopathy, or other localizing signs. At the time, transmission through ingestion and inhalation was not recognized. Review of historical series reveals that many patients diagnosed with typhoidal tularemia had or developed respiratory symptoms,[107,125] and it is possible that these patients would today be classified as having primary pneumonic tularemia.[121] Similarly, some series describe typhoidal tularemia patients with oropharyngeal involvement.[115] Given current understanding about the routes of infection, the term typhoidal tularemia may be outmoded.[92] Clinically, typhoidal tularemia may be confused with any other cause of fever without localizing signs including typhoid fever, brucellosis, Q-fever and other rickettsial infections, infectious mononucleosis, toxoplasmosis, cytomegalovirus disease, babesiosis, malaria, and bacterial endocarditis.

Rare manifestations of tularemia include meningitis,[126,127] pericarditis,[128] endocarditis,[129] and infections of prosthetic devices.[130,131] Although experience with tularemia in immunocompromised patients is limited, patients with impaired cell-mediated infection may be especially susceptible. Sporadic cases of *F. tularensis* infection without an apparent source of infection have been reported in patients with HIV infection,[132] neutropenia following bone marrow transplant,[133] chronic granulomatous disease,[134] stomach cancer,[135] and in patients receiving immunosuppressive therapy.[136,137]

8.2. Laboratory Diagnosis

Laboratory staff must be notified if tularemia is suspected, both to assure optimal testing and to reduce the risk of laboratory-acquired infection. Laboratory diagnosis is usually based on isolation of the organism by culture or detection of elevated antibody titers. Additional testing methodologies are available through public health and reference laboratories, including antigen detection and PCR. Isolates may be subtyped using a variety of molecular techniques (MLVA, PFGE, SNPs), with potential applications in epidemiologic and ecological studies. Gram staining of clinical specimens can be useful to help exclude other etiologies; however the small size of *F. tularensis* makes it difficult to identify by light microscopy.

8.2.1. Isolation and Identification of the Organism. Most clinical isolates are fastidious and require cysteine or cystine for optimal growth. Specimens from enriched sources such as tissue or blood can be plated on sheep blood agar, but recovery from other specimens is best accomplished using chocolate agar, Thayer–Martin agar, cystine heart agar with 9% chocolatized blood (CHAB), buffered charcoal yeast extract, or other cysteine-supplemented agar. Specimens should be incubated at 35–37°C and held for 5 days. On CHAB, *F. tularensis* produces characteristic green or opalescent shiny colonies, allowing for presumptive identification after 24–48 h. Recovery from contaminated or mixed flora specimens can be enhanced using CHAB media supplemented with antibiotics (CHAB-A).[138]

Depending on the clinical manifestations, specimens for culture may include ulcer scrapings or swabs, tissue (e.g., lymph node), lymph node aspirates, sputum, pleural or bronchioalveolar lavage fluid, pharyngeal washes, or gastric aspirates. Recovery of *F. tularensis* from blood culture is uncommon but may be enhanced by use of the BACTEC or equivalent system.[139,140] Primary specimens should be evaluated using Biological Safety Level 2 (BSL-2) precautions; BSL-3 precautions are recommended for work with all suspect cultures. In the United States, the state public health laboratory should be notified if any isolate is suspected of being *F. tularensis*.

Confirmation is based on recovery of an isolate and identification of the culture as *F. tularensis* by antigen detection or PCR.[141] Antigen detection methods include direct fluorescent antibody staining (DFA), slide agglutination, and ELISA.[142] DFA can also be used directly on tissues to yield a presumptive diagnosis of tularemia. Conventional PCR and multitarget real-time TaqMan PCR assays have been developed and are available at some reference laboratories.[141] Automated biochemical identification systems are not recommended for culture identification as they may misidentify the organism.

Once an isolate has been confirmed as *F. tularensis*, supplemental tests can be performed in reference laboratories to identify subspecies and antimicrobial susceptibilities. In Europe, clinical strains can be safely assumed to be type B; however, in North America, both type A and type B commonly cause human infection. *F. tularensis* ssp. *tularensis* (type A) can be differentiated from *F. tularensis* ssp. *holarctica* (type B) strains based on the ability to ferment glycerol and convert L-citrulline to ornithine. Subspecies can also be differentiated using conventional and real-time PCR.[143,144] For susceptibility testing, broth microdilution using cation-adjusted Mueller–Hinton broth (CAMHB) with 2% defined growth supplement can be used (Clinical and Laboratory Standards Institute, 2005). Naturally occurring resistance to antibiotics commonly used for treatment has not been reported.

8.2.2. Serological and Immunological Tests. Because culture of *F. tularensis* can prove difficult, serology is often the basis for laboratory confirmation. Combined immunoglobulin M (IgM) and immunoglobulin G (IgG) against *F. tularensis* can be detected by microagglutination or tube agglutination using whole killed cells.[145,146] A rise in antibody titer is usually detectable within 2–3 weeks of illness onset and may remain for 6–8 months before declining.[147] A single titer of $\geq$1:160 by tube agglutination or $\geq$1:128 by microagglutination is indicative of infection; however, confirmation of recent infection requires a fourfold change in titer between paired specimens, with at least one specimen having a positive titer. Cross-reactions with antibody to *Brucella* have been described.[148] ELISAs directed at LPS are also available, and ELISA combined with Western blot has been shown to have excellent sensitivity and specificity.[149]

8.3. Prognosis

Before the advent of effective antimicrobial therapy, tularemia was characterized by a prolonged convalescence lasting 3 months or longer.[119] When treated promptly with streptomycin, patients improve quickly, some becoming afebrile within 24 h, and most recover completely.[112] Treatment with bacteriostatic agents, including chloramphenicol and tetracyclines, has been associated with relapse if treatment periods are not long enough to allow development of a cell-mediated immune response.[150,151] Other factors associated with poor outcome include underlying medical conditions and delay in seeking treatment.[106] In a recent series where treatment was delayed an average of 8 weeks, 22% of patients treated with streptomycin and 43% treated with doxycycline had persistent or relapsing symptoms.[116] Reported complications of tularemia include suppuration of infected lymph nodes requiring drainage, hepatic abscess,[152] hepatitis,[112,153] renal failure,[106,154] rhabdomyolysis,[139] and adult respiratory distress syndrome.[155]

Estimates of mortality are complicated by differences in the virulence of the two *F. tularensis* subspecies. In Eurasia where only type B strain cause infection, fatal cases are rare. Soviet scientists established early a low mortality rate (<1%) in the USSR due to type B infections.[10] Similarly, no deaths were reported among 1,355 cases reported in Japan from 1924 to 1987,[18] or among 205 cases reported in Turkey from 1988 to 1998, despite the fact that approximately one third were not treated with antimicrobials.[20]

In North America the situation is more complicated as both type A and type B cause illness yet subspecies identification is rarely undertaken. Mortality for some clinical forms can be quite high in the absence of treatment. Five of 123 patients cared for by Kavanaugh before 1932 died, yielding a case fatality rate of 4% overall and 25% among patients with pulmonary involvement.[118] Seventeen (7%) of 225 patients diagnosed at New Orleans Charity hospital before 1946 died, including 12 (57%) of 21 patients with pneumonic involvement.[107] In these and most other early series, pneumonic involvement includes patients with primary pulmonary tularemia and those who developed pneumonia as a complication of other forms of infection, usually ulceroglandular tularemia.

With the advent of antimicrobial treatment, specifically streptomycin, tularemia mortality decreased substantially in the United States. In a review of 339 cases from Louisiana, mortality among patients with pneumonic involvement was only 18% in streptomycin-treated patients, as compared with 80% before the advent of streptomycin.[115] No deaths occurred among 28 Arkansas patients with pneumonic tularemia treated with streptomycin between 1949 and 1969.[122] In a series from the 1980s, four (12%) of 32 patients with pneumonic involvement died, although it is not clear what type of therapy each received. Overall, expected mortality for appropriately treated patients is generally estimated at <1% overall and <5% for patients with pneumonic tularemia.[13]

To better define mortality rates associated with type A and type B infections in the United States, a retrospective study compared outcome for 308 cases for which isolates were submitted to CDC between 1964 and 2004.[38] Contrary to expectations, overall mortality rates were similar: 7% for type B and 9% for type A. Molecular subtyping using pulsed-field gel electrophoresis revealed that type A strains clustered into two distinct genetic groups, one found primarily in the eastern United States and the other primarily in the western United States. Mortality associated with type A east infections was 14%, as compared with 7% for type B infections and 0% for type A west infections. Although the absolute magnitude of mortality in this study is likely elevated due to referral bias, the data suggest a relative difference between the three groups. It remains to be determined whether these differences are related to differences in the virulence of the organism or other factors, such as route of exposure.

9. Control and Prevention

9.1. General Concepts

Prevention of tularemia takes many forms, depending on the likely route of exposure. Use of protective clothing, repellents, or pesticides may help reduce risk of exposure from ticks or other arthropods. Hunters or others who handle

potentially infected animals or tissues should wear gloves to avoid getting the bacteria through cuts or abrasions on their hands. Game meat should be cooked thoroughly and care taken to avoid cross-contamination of other items in the kitchen. Rodents should be excluded from food and water supplies, and drinking water should be chlorinated to reduce risk of infection.

There is scant information on the efficacy of masks or respirators for preventing pneumonic tularemia, especially under field conditions. Use of high-efficiency masks may be prudent when handling hay or other material contaminated by rodents, especially if there is evidence of a die-off in the area. The risk of lawnmower tularemia may be reduced by surveying areas beforehand for animal carcasses and avoiding any dead animals encountered when mowing.

To prevent laboratory-acquired infections, laboratory staff should be notified whenever tularemia is suspected. Processing of clinical samples should be conducted using Biological Safety Level 2 (BSL-2) procedures. BSL-3 procedures should be employed when manipulating cultures or for any activity that could potentially create an aerosol. Isolates presumptively identified as *F. tularensis* at a BSL-2 laboratory should at a minimum be handled in a biosafety cabinet and preferably transferred to a BSL-3 laboratory for further evaluation. In the event of a laboratory exposure, the options are immediate antimicrobial prophylaxis with either ciprofloxacin or doxycycline for 14 days,[13] or a "fever watch" with prompt treatment upon development of fever or other signs of infection within 2 weeks of exposure. Factors to consider in choosing between these options include the number of days elapsed since exposure, the likelihood of an aerosol exposure, and worker anxiety.

Person-to-person transmission of tularemia has never been demonstrated. Therefore, standard hospital infection precautions are considered adequate when managing patients with tularemia.[13]

9.2. Chemotherapeutic Approaches to Prophylaxis

F. tularensis isolates are susceptible to aminoglycosides, tetracyclines, and fluoroquinolones but resistant to many beta-lactams including penicillin, cefuroxime, and imipenem.[13] For treatment of tularemia, streptomycin as long been considered the drug of choice. Treatment with another aminoglycoside, gentamicin, has been more common in recent years. The dose of streptomycin for an adult is 1 g intramuscularly twice daily, and for a child 15 mg/kg twice daily (up to a maximum daily dose of 2 g).[13] Gentamicin may be given intravenously in a dose of 5 mg/kg/day for adults and 7.5 mg/kg/day in children. Several case reports suggest that ciprofloxacin is also effective, although it is not FDA approved for this indication.[13] Streptomycin, gentamicin, and ciprofloxacin should generally be given for 10 days. Bacteriostatic agents, such as tetracyclines, have also been used but are associated with a higher risk of relapse and require longer courses of treatment. Oral or intravenous doxycycline can be effective if given for 14–21 days in a dose of 100 mg/kg twice a day for adults and 2.2 mg/kg twice a day up to a maximum daily dose of 200 mg for children. Ceftriaxone should not be used as several treatment failures have been reported.[151] For prophylaxis following a high-risk exposure, doxycycline or ciprofloxacin is recommended.[13] No natural resistance to antibiotics used for treatment has ever been documented.

9.3. Immunization

The best-studied vaccine for tularemia is the attenuated live vaccine strain (LVS). Developed in the United States using an attenuated type B strain from the Soviet Union, LVS is not licensed for general use. LVS has been evaluated in studies conducted by the United States Department of Defense and is immunogenic when administered intradermally, orally, or by aerosol.[91,156] In aerosol challenge studies using up to 20,000 type A organisms, volunteers immunized intradermally with LVS were protected from infection or had milder illness than controls.[157] Retrospective analysis of laboratory-acquired infections among Department of Defense employees revealed that the incidence of typhoidal tularemia fell from 5.70 to 0.27 cases per 1,000 at-risk employee-years following vaccination with LVS. The incidence of ulceroglandular tularemia remained unchanged; however clinical signs and symptoms were milder.[158] Despite this evidence of efficacy, the protective components of LVS have not been defined, and due to difficulties with standardization, LVS has not been licensed for general use. Development of alternative vaccines is an area of active research.

10. Unresolved Issues

Although virulence differences among strains of *F. tularensis* are well documented, the genetic and molecular determinants of these differences are largely unknown. The ecologic factors underlying the sympatric distribution of different strains of *F. tularensis* are similarly unknown, as are the events that trigger epizootics among host species. Finally, it remains a considerable paradox as to why human-to-human transmission does not occur with such an otherwise highly infectious, airborne pathogen.[159]

CHAPTER 43

Typhoid Fever

Myron M. Levine

1. Introduction

Typhoid fever is an acute generalized infection of the reticuloendothelial system, intestinal lymphoid tissue, and gallbladder caused by *Salmonella enterica* serovar Typhi (*S.* Typhi). This communicable disease is restricted to human hosts and humans (chronic carriers) serve as the reservoir of infection. A broad spectrum of clinical illness can ensue, with more severe forms being characterized by persisting high fever, abdominal discomfort, malaise, and headache. In the preantibiotic era, the disease ran its course over several weeks, resulting in a case fatality rate of approximately 10–20%.[1,2] The protracted, debilitating nature of this febrile illness in untreated (or improperly treated) patients is accompanied by mental cloudiness or stupor, which gave rise to the term "typhoid," meaning stuporlike. Paratyphoid fever is the clinically similar febrile infection caused by *S.* Paratyphi A or B (or more rarely C). Typhoid and paratyphoid fevers are also referred to as enteric fevers. In most endemic areas, typhoid comprises approximately 80% of enteric fever.

Typhoid infection is virtually always acquired by ingestion of food or water vehicles contaminated by human excreta that contains *S.* Typhi. Typhoid fever is extremely uncommon in modern industrialized countries where populations have access to treated water supplies and sanitation that removes human waste. In contrast, among populations in less-developed countries that lack such amenities, typhoid fever is often endemic and, from the public health perspective, typically constitutes the most important enteric disease problem of school-age children.[3] Besides school-age children in less-developed countries, two other populations are at recognized risk of typhoid: travelers and clinical microbiologists. Typhoid fever occurs with variable frequency among travelers from industrialized countries who visit less-developed areas of the world. Among US travelers, the risk is highest with travel to the Indian subcontinent, Mexico, Central America, the Philippines, and Haiti.[4,5] Clinical microbiologists, including those in industrialized countries, have increased exposure to *S.* Typhi and therefore also constitute a high-risk group.[6,7]

Typhoid fever is readily treated by prompt administration of appropriate antibiotics if strains are susceptible.[8] Since 1990, strains of *S.* Typhi exhibiting resistance to most of the antimicrobials that previously were clinically effective have spread aggressively throughout the Indian subcontinent, Southeast Asia, and the Middle East.[9–12] A few antibiotics that are effective against these multiply resistant strains are expensive and not readily available in rural areas of less-developed countries. Thus, the arrival on the scene and dissemination of these multiply resistant *S.* Typhi constitute an increasing public health crisis in many less-developed countries.

2. Historical Background

Prior to the early decades of the nineteenth century, typhoid fever was not recognized as a distinct clinical entity and often was confused with other prolonged febrile syndromes, particularly typhus fever of rickettsial origin. Debate continues over who first clearly differentiated typhus fever from typhoid (i.e., typhus-like) fever,[13] as medical historians have variously bestowed credit for this clinical clarification upon Huxham (1782),[13a] Louis (1829),[13b] Gerhard (1837),[13c] and Schoenlein (1839).[13b,d]

In 1829, Bretonneau[13e] described a severe enteric infection occurring in young Parisians and used the term "do-thientérite" ("boil of the intestine") to describe

the lesion that can lead to intestinal perforation. Louis catalogued the abnormal lesions in the intestine, lymph nodes, spleen, and skin (rose sports) in 158 patients and describes hemorrhage and perforation in the gut. During this period, the intestinal lesions were thought to be a complication or unusual extension of typhus fever.

Gerhard,[13c] working in Philadelphia, contended that two similar yet distinct febrile illnesses exist that are nevertheless discernable from one another on the basis of pathological findings: one (typhoid) exhibits prominent intestinal lesions. Schoenlein referred to two distinct forms of typhus, "exanthematicus" and "abdominalis." However, it is William Jenner who, circa 1850, definitively dispelled controversy on the subject by providing precise clinical descriptions and pathological observations from postmortem examinations that allowed a clear-cut differentiation between the two illnesses. Jenner argued that the pathological lesions in Peyer's patches and mesenteric lymph nodes were peculiar to typhoid and were never seen with typhus. In 1847, the term "enteric fever" was introduced in an attempt to replace typhoid fever and avoid confusion with typhus. While this term is frequently used, it never supplanted the more common usage of typhoid and paratyphoid fever.

In William Budd's 1873 milestone in epidemiology,[14] *Typhoid Fever: Its Nature, Mode of Spreading and Prevention*, he clearly described the contagious nature of the disease and incriminated fecally contaminated water sources in transmission, years before the causative organism was identified. Eberth (1880)[13f] visualized the causative bacilli in tissue sections from Peyer's patches and spleens of infected patients, while Gaffky (1884)[13g] grew it in pure culture. Known in earlier years as *Bacillus typhosus, Eberthella typhosa*, and *S. typhosa*, it is presently referred to as *S.* Typhi; the lack of italics and capital T indicates that taxonomically this bacterium is now considered a serovar of *S. enterica* and not a separate species.[15]

Typhoid fever was endemic in virtually all countries of Europe and North and South America in the late nineteenth and early twentieth centuries. A single intervention – the treatment of water supplies (by chlorination, sand filtration, or other means) – which became increasingly popular in the late nineteenth and early twentieth centuries, broke the cycle of endemicity and caused the incidence of typhoid fever to plummet drastically, even though the prevalence of chronic carriers in the populations remained high for decades thereafter.[16,17]

Inactivated (heat-killed, phenol-preserved) *S.* Typhi were utilized as parenteral vaccines as far back as 1896 by Pfeiffer and Kolle in Germany and Wright in England.[13] Wright administered his vaccine (three doses 2 weeks apart) to two medical officers in the Indian Army, one of whom thereafter ingested wild typhoid bacilli without developing illness. Thereafter, Wright tested his vaccine in 2,835 volunteers in the Indian Army. While local and generalized adverse reactions were common, the results were considered to be sufficiently encouraging for a decision to be made to vaccinate troops embarking for the Boer War in South Africa. Outcry over the frequency of adverse reactions led to a suspension of vaccination. However, on Wright's insistence, a board of enquiry was assembled to review data on the reactogenicity and efficacy of the vaccine. The committee concluded that the vaccine was efficacious and that its value in preventing typhoid fever exceeded the price paid in adverse reactions. Consequently, by World War I, typhoid vaccination became virtually routine in the British Army.

Randomized, placebo-controlled, field trials in the 1960s established the efficacy of the heat-phenolized and acetone-inactivated parenteral whole cell vaccines.[18–22] Although these vaccines were shown to confer moderate protection that persisted for up to 7 years, they never became well-accepted public health tools because they frequently caused systemic adverse reactions (about 25% of recipients developed fever and malaise).[18,19,23] The parenteral killed whole cell vaccines have been supplanted by two newer vaccines: attenuated *S.* Typhi strain Ty21a used as a live oral vaccine and purified Vi capsular polysaccharide utilized as a parenteral vaccine.[3] These two newer vaccines, which are at least as effective as the parenteral whole cell vaccines but are well tolerated, are licensed and available in many countries and constitute credible public health tools.

3. Methodology

In the United States, the occasional sporadic cases and rare outbreaks of typhoid fever that occur are regarded as infectious disease calamities that rivet the attention of public health officials. Extensive investigative efforts are mobilized to identify the individual, usually an asymptomatic carrier,[24,25] who has served as a source of the outbreak or of sporadic cases (when they occur among persons who are not recently returned travelers). Carriers are carefully identified and regularly followed by city or county health departments. Such monitoring ensures that carriers do not participate in occupations wherein they might contaminate food or water consumed by the public at large.

In less-developed countries where typhoid fever is endemic and public health resources are scarce, epidemiological investigations may be initiated only when a large-scale outbreak occurs or there is an unusual increase in the number of sporadic endemic cases.[26]

3.1. Sources of Mortality Data

Information on deaths from typhoid fever in the United States derives from two sources, the first of which is notifications published within the *Morbidity and Mortality Weekly Report* (MMWR). The second source, available since 1975, is the Centers for Disease Control and Prevention (CDC) typhoid case report form, which is completed by state and community health departments on all bacteriologically confirmed cases of typhoid fever.

Before antibiotic therapy was available, a proportion of typhoid deaths were attributed to intestinal hemorrhage or perforation followed by peritonitis. Other patients in that era died of complications rarely seen today, such as myocarditis, pneumonia, and meningitis.[1] However, most fatal cases of typhoid fever resulted from inanition consequent to several weeks of unremitting fever and obtundation without a recognized specific complication.

In the preantibiotic era, a more accurate estimate of the relative importance of typhoid fever as a public health problem could be obtained by consideration of typhoid mortality rates per 10^5 population than by reviewing incidence rates. This was true because milder cases of typhoid fever can be confused with other febrile syndromes and bacteriological confirmation was undertaken in only a small proportion of suspect cases; in contrast, typhoid deaths are fairly definitive. Indeed, if autopsy is performed, the ileal lesions of gut-associated lymphoid tissue are pathognomonic of typhoid or paratyphoid. Beginning in 1913, epidemiological data on typhoid mortality in large cities in the United States were summarized annually in the *Journal of the American Medical Association*.[17] In the period 1911–1915, annual typhoid death rates in the nine most populous US cities (New York, Chicago, Philadelphia, Detroit, St. Louis, Boston, Pittsburgh, Cleveland, and Baltimore) ranged from $8.0/10^5$ (New York, Boston) to $23.7/10^5$ (Baltimore).[17] Over the next decade it was possible to monitor the extraordinary effect that the rapidly increasing availability of treated water supplies had on diminishing typhoid mortality.[16]

The modern antibiotic era of typhoid epidemiology was ushered in by Woodward et al.[27] in 1948, when they demonstrated that chloramphenicol was highly effective in the treatment of this disease. Over the next 25 years, widespread use of this oral, inexpensive, effective antibiotic markedly diminished the case fatality rate of typhoid fever. Prior to the advent of chloramphenicol therapy, the case fatality rate of typhoid fever typically ranged from 10 to 20%, irrespective of where cases occurred worldwide. Presently, deaths from typhoid in the United States are distinctly rare, with only two deaths reported in the period 1996–2001 (one death in 1996 and the other in 2001).[28] Ironically, since antibiotics have become widely available worldwide, mortality statistics are no longer a reliable measure of the endemicity of typhoid fever in populations.

3.2. Sources of Morbidity Data

The vast majority of cases of typhoid fever diagnosed by clinicians in the United States are reported to state or local health departments. Many cases are reported directly by physicians. In addition, all positive stool, blood, bile, bone marrow, or other cultures that yield *S.* Typhi are reported by the laboratories making the isolations. The same two reporting systems mentioned above with respect to mortality also provide morbidity data.

In many less-developed countries with endemic disease, incidence data on typhoid tend to be unreliable and are distortions of the true disease burden; these distortions are usually under estimations but may also be over estimations. Many "fever" hospitals in developing and transitional countries record the number of patients admitted with the clinical diagnosis of typhoid fever, while others that have bacteriological capability report just the number of confirmed cases. The true incidence of typhoid fever in many less-developed countries is not known because the paucity of bacteriological capability precludes most suspected cases from being confirmed; moreover, suppression of disease by self-medication with antibiotics or by health practitioner treatment without obtaining cultures and incomplete reporting further distort the true situation.

3.3. Surveys

Several types of surveys have been carried out in recent years to study the epidemiology of endemic or epidemic typhoid. These include the following:

1. Bacteriological surveys of exposed populations during outbreaks[24,26,29] or household contacts of sporadic cases,[30] in order to detect subclinical and mild cases and carriers.
2. Systematic collection of blood cultures among febrile patients to confirm the incidence of *S.* Typhi infection in certain populations (Table 1).[31–37]
3. A combination of serological screening tests (for elevated serum titers of Vi antibodies) and bacteriological confirmation (by means of multiple stool cultures and bile-stained duodenal fluid cultures) to detect chronic biliary carriers of *S.* Typhi.[24,38–42]
4. Serosurveys to measure the prevalence of H antibodies in different age groups, as a measure of the cumulative contact with *S.* Typhi.[43,44]

Surveys of family members and persons known to be associated with an outbreak of typhoid fever are usually performed by culturing three successive stool specimens from asymptomatic subjects. One or more of these three

[a]The investigators established multiple (no-cost) treatment centers in the urban area under surveillance to facilitate febrile patients seeking health care and blood cultures were collected at these centers. They also arranged, as necessary, transport of patients to hospital.
[b]Residents of the Kalkaji cohort were visited twice weekly in their households to detect persons with fever. For persons <5 years of age a blood cultures was obtained if the temperature was ≥38°C, irrespective of the duration of fever. In contrast, for persons ≥5 years of age, fever had to be present for 3 days before a blood culture was taken.

specimens will yield the organism in most carriers (>80%); chronic carriers are persons who shed *S.* Typhi in the stool for more than 1 year. Exposed individuals who are in the incubation period before illness can also have positive stool cultures.[45] Culture of bile-stained duodenal fluid by means of string capsule devices (Enterotest, HEDECO, Mountain View, CA) can often confirm the biliary carrier state in epidemiologically incriminated individuals who have negative stool cultures.[46] Alternatively, administering a laxative to individuals whose stool cultures are initially negative, leading to passage of one or more loose stools, often results in the cultures then becoming positive. The explanation for this increased stool culture sensitivity is that consequent to the laxative, typhoid bacilli from the bile are now rapidly excreted, having little exposure to the hostile environment created by the normal flora of the large intestine.

Systematic collection of blood cultures, in particular prior to and during efficacy trials of vaccines, has established the incidence of confirmed typhoid in many populations (Table 1).[47–55] Often these surveys yield rates that are much higher than were predicted, particularly in pre-schoolchildren.[32] Systematic surveys in some endemic areas demonstrated a surprising frequency of bacteremic typhoid infection among infants and toddlers[31,36,56]; in Chile and Peru these infant bacteremias due to *S.* Typhi were associated with only mild, self-limited febrile illness.[31,56]

In some other areas where bacteremia in febrile infants was systematically studied, the isolation of *S.* Typhi was rare in infants <12 months of age.[32,34,35,37,57] Elevated titers of serum IgG antibodies directed at the capsular Vi polysaccharide antigen that covers *S.* Typhi are encountered in >80% of chronic biliary carriers of *S.* Typhi but only rarely in healthy individuals[40]; <20% of persons with acute typhoid fever manifest elevated Vi titers. Therefore, the measurement of Vi antibodies has been repeatedly utilized with success as a screening test in nonendemic and endemic areas to detect chronic carriers.[24,38–42,58]

Serum H antibodies are IgG and long lived. However, they may be the consequences of stimulation by typhoid vaccination or by contact with other serovars of *Salmonella* that express the same Phase 1 flagellar antigen (d) as Typhi but have distinct O antigens.[43] Therefore caution must be exercised in selecting the populations to be sampled and in interpreting the results of serosurveys. Nevertheless, seroepidemiological surveys in which antibodies to *S.* Typhi flagellar antigens (H) are measured in different age groups have proven quite useful in comparing the prevalence of *S.* Typhi infection in different populations of interest and in estimating the age of peak infection.[43,44]

3.4. Laboratory Diagnosis

3.4.1. Isolation and Identification of the Organism. Confirmation of the diagnosis of typhoid fever requires recovery of *S.* Typhi from a suitable clinical specimen. Because of their practicality and relative ease of access, multiple blood cultures should be obtained from patients in whom the diagnosis is suspected clinically. The rate of recovery of *S.* Typhi in blood cultures depends on many factors, including the volume cultured, the ratio of the volume of blood to the volume of culture broth in which it is inoculated (ideally, the ratio should be ≥ 1:8), inclusion of anticomplementary substances in the medium (such as sodium polyanethol sulfonate or bile), and whether the patient has already received antibiotics to which the *S.* Typhi is sensitive. If three 5 ml blood cultures are obtained, *S.* Typhi can be recovered from the blood in approximately 70% of suspect cases.

The current "gold standard" of bacteriological confirmation of typhoid fever is the bone marrow culture, which is positive in 85–95% of cases, even when the patient has received antibiotics.[59–62] The use of duodenal string devices to obtain bile-stained duodenal fluid for culture is also quite useful. The combination of a duodenal string and two blood cultures generally provides a sensitivity of bacteriological confirmation equal to that achieved with bone marrow cultures, but without the invasiveness of the latter.[60] The bacteriological culture of skin snips from rose spots also provides a high yield.[59] Stool cultures generally lead to recovery of the organism in only 45–65% of cases. The yield tends to be somewhat higher in children.

S. Typhi does not ferment lactose; it produces H_2S but does not produce gas. As a consequence, suspicious colonies are evident on usual lactose-containing media as lactose-negative colonies. The biochemical pattern in triple sugar iron agar is rather characteristic, manifested by an acid butt without gas, an alkaline slant, and obvious H_2S production. Fresh isolates typically agglutinate with Vi but not group D antiserum. However, if the bacteria are boiled to remove the Vi capsule, a reaction with group D antiserum is then readily seen. The Vi antigen is an important epidemiological aid, since its susceptibility to lysis by bacteriophages allows for the classification of 80 definite and stable varieties of typhoid bacilli. This can help identify the source and spread of a specific strain.[63] The CDC is the principal source of phage typing in the United States. A more modern, very useful, molecular epidemiological tool for comparing isolates is the analysis of pulsed field gel electropherotypes of isolates.[64–68]

Polymerase chain reaction (PCR) methods, in theory, can be applied to clinical specimens to expedite a microbiological diagnosis of *S.* Typhi infection.[69,70] However, heretofore these methods have been amenable only to research and reference laboratories, since they are impractical for routine use in most laboratories in endemic areas that support clinical facilities. Moreover, significant hurdles will have to be overcome to adapt them to become inexpensive, simple point-of-care tests for use in clinical situations. In contrast, PCR methods are becoming increasingly attractive and practical to serotype *Salmonella* strains once they have been isolated from blood and other cultures.[71]

3.4.2. Serological Diagnostic Methods. Serodiagnosis of typhoid fever has been pursued since the late nineteenth century (1896) when Widal and Sicard[72] showed that the serum of patients with typhoid fever agglutinated typhoid bacilli. The Widal test, still practiced today in many areas, involves the search for agglutinins in the patient's serum. Whereas the test may be performed with antigen in tubes or on slides, the former is generally more accurate. By careful choice of antigen, both O and H antibodies can be selectively measured. By use of *S.* Typhi strain O901, which lacks flagellar and Vi antigens, *S.* Typhi O antibody can be selectively measured. To detect antibodies against the appropriate H antigen (d), a strain such as *S.* Virginia is selected that possesses the identical Phase 1 flagellar antigen (d) as *S.* Typhi but shares no O somatic antigens with serovar Typhi.[43] Most patients with typhoid fever have elevated levels of O and H

antibody at the time of onset of clinical illness.[43] Anderson and Gunnell[73] emphasized the importance and usefulness of H titers in serodiagnosis of typhoid fever. However, in general, the prevalence of H antibodies in adults living in endemic areas is too high for the test to be useful in that age group.[43,44] Nevertheless, it can be helpful in children less than 10 years of age in endemic areas and in persons of any age from nonendemic areas.[43] A history of inoculation with parenteral killed whole cell vaccines invalidates the use of the Widal test. One study from Indonesia supported the use of the slide test for O agglutinins of *S.* Typhi, even for adults in that endemic area.[74]

Serological tests that measure Vi antibody by passive hemagglutination or enzyme-linked immunosorbant assays (ELISAs), using highly purified Vi antigen, are excellent to screen for chronic *S.* Typhi carriers, most of whom have highly elevated levels of Vi antibody.[24,38–42,58] In contrast, Vi antibody tests are of little help in diagnosing acute typhoid fever because only a minority of patients with acute infection have detectable Vi antibody.[38,40]

3.4.3. Rapid Immunoassays. Over the years many attempts have been made to develop tests that detect *S.* Typhi antigens in blood, urine, or body fluids, thereby providing a rapid diagnostic test for typhoid fever. With few exceptions these tests have been disappointing and have failed to warrant the enthusiasm of the initial reports. Most of these assays are based on the detection of the O or Vi antigens of *S.* Typhi in blood or urine using coagglutination, ELISA, or countercurrent immunoelectrophoresis. Two other tests, TyphiDot and TUBEX, that detect antibodies to *S.* Typhi are currently under evaluation.[75–78] Although neither test is completely satisfactory, in some venues results have been guardedly promising.[75–78]

4. Biological Characteristics of the Organism

The taxonomy of *Salmonella* has changed repeatedly during the past 30 years, leading to considerable confusion.[15] Most authorities presently use the term, *S.* Typhi, to refer to the serovar that is the causative organism of typhoid fever. Since it is now considered a serovar and not a separate species, Typhi is written non-italicized and with a capital T. Serologically, *S.* Typhi falls into group D *Salmonella* on the basis of its O antigens 9 and 12, with 9 being the immunodominant epitope diagnostic of Group D. *S.* Typhi is motile and its peritrichous flagellae bear flagellar (H) antigen d, which is also encountered in approximately 80 other bioserotypes of *Salmonella*. A few percent of isolates from Indonesia have flagellae that bear other antigens including (j) (which results from an internal deletion within the *fliC* gene encoding (d))[79] and z66 (which may be found in conjunction with (d) or (j)).[80] Strains freshly isolated from patients possess on their surface an acidic polysaccharide capsule, the Vi (for virulence) antigen.[81] Vi prevents O antibody from binding to the O antigen and inhibits the C3 component of complement from fixing to the surface of *S.* Typhi.

S. Typhi exhibits a remarkable degree of homogeneity, rarely showing biochemical or serological variability. Exceptional are the few percent of isolates from Indonesia that bear phase 1 flagellar antigen j rather than d. Some Indonesian isolates express flagellar antigen z66, in addition to d or j. In practical terms, phage typing, using Vi phages, offers a reasonable tool that is often helpful in differentiating strains from different geographic areas.[39] Molecular epidemiological techniques such a multi-locus sequence typing that are useful with other bacteria are not helpful in differentiating *S.* Typhi isolates but rather corroborate the homogeneity of *S.* Typhi strains from diverse areas and time periods.[82] Similarly, analysis of the complete genome of two *S.* Typhi strains shows an impressive level of homogeneity.[83,84] PFGE is one molecular typing method that has proven useful for studying the epidemiology of *S.* Typhi.[64,68,85,86]

Typhoid bacilli are able to achieve an intracellular habitat promptly after oral ingestion. This property may account for the prolonged duration of disease in untreated patients and the relatively slow response to antibiotic therapy. Within macrophages of the reticuloendothelial system, the organism appears to be protected from the host's humoral immune mechanisms, and in this intracellular niche it also resists the effect of many antibiotics.

Like other gram-negative bacilli, the outer portion of the cell wall of typhoid bacilli consists of lipopolysaccharide (LPS) or endotoxin. This substance, which has biological properties that are important in the pathogenesis of typhoid fever, consists of three layers, the outermost being made up of a repeating sequence of sugars that determines the specificity of the O antigen. For typhoid, there are two O antigens, immunodominant epitope 9 and minor epitope 12. Rough mutant strains that lack the outer layer of LPS are nonpathogenic. The middle LPS layer is the R core. The inner layer of LPS is the lipid A endotoxin moiety. Endotoxin is pyrogenic and triggers the complement and clotting cascades; it also stimulates the release of cytokines that are deemed responsible for many of the clinical features of typhoid fever.

A curious feature of *S.* Typhi is that, in contrast with many other pathogenic enterobacteriaceae (e.g., *Shigella*, nontyphoidal *Salmonella*) that readily accept and stably carry R factor plasmids encoding antibiotic resistance, until $\sim$ 1990 this was the exception rather than the rule

with typhoid bacilli. Chloramphenicol, the first antibiotic used to treat typhoid fever, held a position of prominence for 25 years and is still important in less-developed countries where prevalent strains of *S.* Typhi remain susceptible. Then, rather abruptly, large-scale epidemics of chloramphenicol-resistant typhoid fever occurred, first in Mexico (1972)[87,88] and then in Southeast Asia (1974)[89]; sporadic cases of resistance were reported from the Middle East and India. Curiously, after approximately 2 years in Mexico, the resistant strain disappeared and was replaced by chloramphenicol-sensitive strains. Oral amoxicillin and trimethoprim–sulfamethoxazole were shown to be satisfactory alternatives for treating patients with chloramphenicol-resistant typhoid fever.[88] In 1979 and 1980, a similar abrupt appearance of chloramphenicol-resistant typhoid occurred in Lima, Peru;[90] these resistant strains also disappeared after a few years and were again replaced by chloramphenicol-sensitive *S.* Typhi. It is notable that in each of these instances the antibiotic-resistance genes were encoded on plasmids of incompatibility group H1.[87,90] A plausible biological explanation has never been found for the sudden appearance and regression of *S.* Typhi carrying these plasmids.

Beginning circa 1989, strains of *S.* Typhi resistant to chloramphenicol, amoxicillin, and trimethoprim–sulfamethoxazole disseminated widely throughout Asia, constituting a public health calamity until several years into the millennium.[9–11] Alternative effective antibiotics, including oral ciprofloxacin and parenteral ceftriaxone, are expensive and have other drawbacks. Moreover, the widespread use of ciprofloxacin and other fluoroquinolones, often in inadequate dosages and duration, selected for the emergence of fluoroquinolone-resistant strains.[12]

One other relevant biological property of *S.* Typhi is its ability to survive for a relatively long time in certain environmental niches, as in snow and surface waters, and in some foods. In some circumstances, typhoid bacilli may survive for several months, a property that has resulted in some "unexpected" epidemics because no recent source for the contamination was found.

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

5.1.1. In the United States. Figure 1 shows the annual incidence rate of reported cases of typhoid fever in the United States per 10^5 population (data include Hawaii and Alaska, even before statehood) from 1950 to 2006. There was a leveling of the curve in the mid-1960s at about 2.0 cases/10^5 population and that incidence continued until the late 1990s. The spike in 1973 was due to the large waterborne outbreak that occurred in Dade County, Florida.[29,91] In that outbreak, the water supply in a migrant labor camp became contaminated and 222 cases of typhoid fever ensued. In the period 1989–1993, there were, on average, 473 cases of typhoid fever reported annually (range, 414–552),[92] whereas in the period 1994–2006, the average annual number of reported cases was 363 (range, 321–441).

S. Typhi infections in the United States were reviewed by the CDC for the period 1975–1984, representing a decade of experience beginning shortly after the Dade County outbreak;[93] 4,641 cases were reported to the MMWR during this period. More detailed epidemiological information was available for 2,666 of these cases for whom CDC special questionnaire forms were completed (57% of the cases). Twenty-nine deaths were reported, including 21 among domestically acquired cases and 8 among returned travelers. Mortality was five times higher for domestically acquired cases than for foreign travel-acquired cases (2.5 versus 0.5%). Among the domestically acquired cases, 9% were related to contact with a previously diagnosed typhoid carrier and 21% were related to contact with a newly diagnosed carrier. Although overall the majority of cases acquired domestically in the United States are single cases, 28% (266 of 934) of cases were related to outbreaks. During this decade of surveillance experience, there were three major outbreaks, all food-borne.

Travel-related cases of typhoid fever have increased notably since 1967,[4,5,94–96] so that by the time of the CDC review for the period 1975 through 1984,[93] 1,653 of the 2,666 reported cases (62%) were acquired during foreign travel. The median age for the 1,371 travel-related cases was 23 years, whereas that of the 857 cases acquired in the United States was 20 years. Two subsequent reports from the CDC that analyze typhoid fever cases among US citizens in the periods 1985–1994[4] and 1994–1999[5] also emphasize the importance of foreign travel. In the period 1985–1994, 72% of US cases of typhoid fever were associated with foreign travel and visits to six countries accounted for 80% of the travel-associated cases (Mexico, 28%; India, 25%; the Philippines, 10%; Pakistan, 8%; El Salvador, 5%; and Haiti, 4%). Coincident with the pandemic of multiple antibiotic-resistant typhoid fever in South Asia that began in 1989 and extended through the 1990s, the risk of developing typhoid fever among travelers to the Indian subcontinent was impressively high during the period 1990–1994 and exceeded 1,000/10^6 travelers; this is comparable to incidences observed in populations living in areas of moderate typhoid endemicity. Notably, the risk of developing typhoid fever in these travelers was usually associated with exposure lasting less than one month.

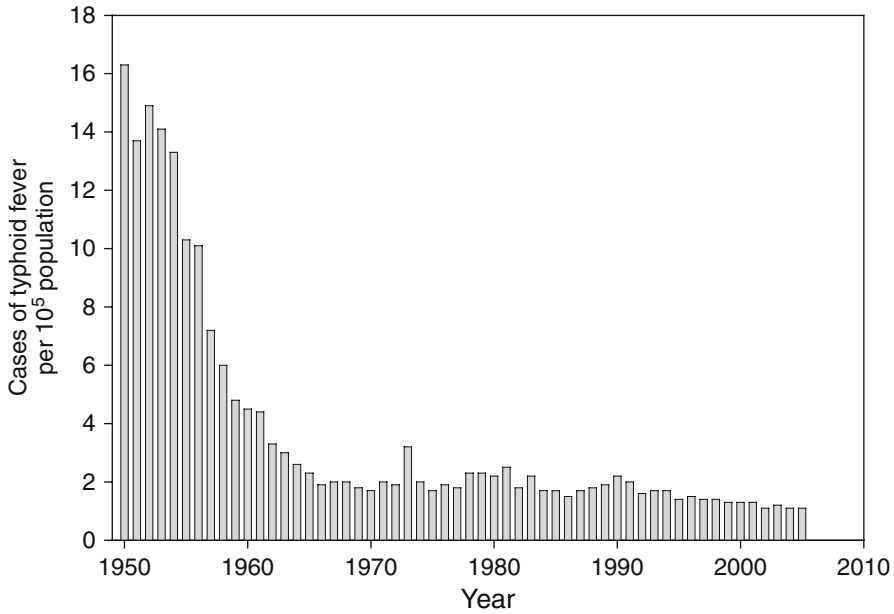

Figure 1. Typhoid fever by year, United States, 1950–2006.

In the period 1994–1999, 1027 of 1,393 (74%) US cases of typhoid fever were associated with foreign travel. Once again, travel to six countries accounted for 76% of the travel-associated cases.[5] During this period, travel to the Indian subcontinent represented the greatest risk (Table 2). Among patients who indicated a single reason for their travel, 80% were visiting family in the foreign country, whereas only 3% were tourists and 1% were on business-related travel.[5] Reviewing the CDC data from travel-associated cases of typhoid fever, Steinberg et al. report that among 626 travelers to a single country who reported their duration of stay, 16% were in the foreign country for < 2 weeks and 37% for less than 4 weeks.[5]

5.1.2. Worldwide. The WHO records the incidences sent to it by cooperating countries. These figures indicate that typhoid remains a major public health problem in South and Southeast Asia, the Middle East, Northeast Africa, sub-Sahara Africa, Central America, some parts of the Caribbean, and a few areas of South America. In endemic areas notification data appear to be a gross underestimation due to

incomplete reporting and insufficient means for bacteriological confirmation. However, it is difficult to quantitate the true magnitude of the typhoid fever problem worldwide because the clinical picture is confused with many other febrile infections and the capacity for bacteriological confirmation is absent in most areas of the less-developed world.[97,98] Nevertheless, the most recent exercise to quantify the global morbidity and mortality burden of enteric fever estimates that each year there occur circa 21.6 million cases of typhoid fever and 216,510 deaths; it is also estimated that there occur $\sim$ 5.4 million cases of paratyphoid fever.[98]

Population-based surveillance for enteric fever undertaken by the systematic collection of blood cultures from febrile patients provides hard data on the incidence of typhoid and paratyphoid fever in different populations, age groups, and geographic areas (Table 1). However, several factors affect the sensitivity of such surveillance. These factors include whether the surveillance is passive, active, "modified passive", or "modified active"; the volume of blood collected and the antibiotic treatment practices. By passive surveillance is meant the fact that febrile cases are detected when the patient seeks health care at a treatment facility. "Modified passive" indicates that special healthcare facilities were introduced specifically to bolster the existing system and increase the access of febrile patients to health care to enhance surveillance. Active surveillance implies that investigators visit households at a certain frequency (e.g., 1–2 times per week) to take temperatures of subjects; the febrile subjects then either have blood cultures collected in the household or the febrile subjects are sent to a nearby health facility where they are cultured. "Modified active" surveillance means that household visits are made to detect patients with fever but that instead of either drawing blood cultures or arranging for the subject to go to a health facility for collection of a blood culture the subject is merely "encouraged" to go to a facility to have a blood culture. Over the past 25 years there have been multiple studies that have involved blood culture-based surveillance of enteric fever, either to assess the population disease burden or as part of controlled field trials to measure the efficacy of vaccines. Results of these studies are shown in Table 1 with the data adjusted to represent annual incidence rates.

Surveillance data generated by quantitating the incidence of bacteriologically confirmed typhoid fever in placebo groups participating in large-scale field trials of typhoid vaccines[47,49–54] or in preparation for undertaking vaccine field trials[35,37] show annual incidence rates from 103 to $>$1,000 cases per 10^5 population in typhoid-endemic areas (Table 1). Several major assumptions or "corrections" must be made if one is intending to extrapolate from local data that involve unusually intense surveillance methods in order to estimate the disease incidence and burden for larger populations within which the surveillance populations lie (e.g., entire country or regions of continents). It is widely agreed that data from such local surveillance in fact underestimate the overall enteric fever burden. Among the factors believed to result in the underestimate are that many patients will have received antibiotics prior to having a blood culture, resulting in a false-negative culture. Also, patients with milder forms of enteric fever may be treated with antibiotics as ambulatory patients and never have a blood culture, thereby constituting undetected cases. On the other hand, intensive surveillance studies in relation to vaccine field trials or vaccine impact projects typically take place in populations in which it is already known that typhoid fever and paratyphoid fever exist ("hot spots"), although precise quantification of the incidence may not be available before special surveillance studies are introduced. Since the prevalence of *S*. Typhi and *S*. Paratyphi are geographically spotty, one must be cautious in making extrapolations. To give one example, during the 1970s and 1980s, when typhoid and paratyphoid fever were hyper-endemic in Santiago, Chile, enteric fever was observed at a much lower incidence in most other parts of the country. Clinical observations, notification data and seroepidemiologic studies all corroborated this geographic difference in distribution of the disease.[44] Yet exercises to approximate the typhoid fever disease burden for all of South America extrapolated incidence data from Santiago field trial control groups to the population of the entire continent.

5.1.3. Prevalence of Carriers. The total number of typhoid carriers in the United States is not known. In 1962, the number was estimated to be 3,637 and in 1978 more than 2,000. In Arkansas, the rate of carriers was 3–4/10^5 population in 1978. Many of the known carriers are elderly, and with the low incidence of typhoid fever in this country, few new indigenous carriers will appear to replace those who will die in the next decade. However, the influx in recent years of immigrants from Central America and South and Southeast Asia undoubtedly includes some chronic typhoid carriers from these endemic areas. Nevertheless, in view of the well-developed sanitary conditions existent throughout the United States, there are no grave epidemiological consequences anticipated from the arrival of such carriers unless they become employed as food handlers.[24]

In the preantibiotic era in the United States, some predictions were made about the decline in numbers of carriers; these predictions have come true. The estimated carrier prevalences in 1935 for Massachusetts and Mississippi were 48 and 288/10^5 population, respectively. In New York, in 1940, there were an estimated 2,490 carriers, for a prevalence

of 41.8/100,000 population.[99] According to the 1943 report by Ames and Robins[99] of the New York State Department of Health, the number of carriers in New York would have fallen from 2,490 in the early 1940s to about 190 by 1980. Their assumptions in arriving at these figures did not predict the effect antibiotic therapy (unavailable in their time) would have on the development of and treatment of the carrier state. Nonetheless, in New York in 1980, the total number of known carriers was 175, remarkably close to the 190 predicted 37 years earlier by Ames and Robins.

Only a few quantitations have been made of the prevalence of chronic carriers in less-developed countries. One such survey carried out in Santiago, Chile, during a period when typhoid fever was highly endemic, estimated a crude prevalence of 694 carriers/10^5 population.[100] This high prevalence was related in part to the high prevalence of cholelithiasis in the adult female population of Santiago.[101]

5.1.4. Prevalence of Antibody. The prevalence of antibodies to O, H, and Vi antigens in US citizens in the late 1960s and early 1970s could be estimated from the extensive serological data accumulated in the course of a unique series of volunteer studies with wild-type *S.* Typhi conducted to evaluate the efficacy of typhoid vaccine.[45] Baseline antibody titers (obtained at time of entry into the study) revealed that older men had higher geometric mean H antibody titers than those 15–20 years their junior. The earlier the year of birth, the more likely a volunteer was to show an elevated titer of H antibody at the time of participation in the study, and if birth occurred after 1935, a period when the disease was rapidly disappearing in the United States, the influence of age disappeared. These values held whether or not there was a military history, i.e., an opportunity to have received vaccine. Since these studies investigated persons living in a nonendemic area, the percentages of volunteers lacking detectable O, H, and Vi gave an estimate of the lack of past exposure to *S.* Typhi antigens, whether by previous disease, vaccine administration, or exposure to other salmonellae-containing common and cross-reacting O, H, or Vi antigens. Thus, of 331 men, 52% had no detectable H, 74% no detectable O, and 42% no detectable Vi serum antibodies. The majority of the younger volunteers participating in the later phases of the study fall into these groups. Of those men who had demonstrable circulating antibody titers, only a small percentage had elevated values. If the trend noted in that study continued, one would expect an even smaller percentage of current US citizens to have detectable antibodies as opportunities for exposure to typhoid antigens in the United States continue to diminish. This hypothesis is predicated on the assumptions that (1) the sources of acquired disease will continue to decline, i.e., fewer carriers will develop and the present ones will die off; (2) there will be continued minimal utilization of typhoid vaccine in this country; (3) the number of immigrants to the United States from typhoid-endemic areas (e.g., South Asia, Haiti) will not be so large as to affect markedly the prevalence of antibodies; (4) there will be better control over other sources of salmonellae that may have cross-reacting antigens. More than 140 serovars of *Salmonella*, some of which commonly cause gastroenteritis, have O antigens that cross-react with the typhoid bacillus antigens in the Widal agglutination test. Similarly, there are at least 70 strains with cross-reacting H antigens, although few of these have been recognized in association with human clinical illness. These antigens may be the source of "typhoid" O and H antibodies detected by the Widal test in many US citizens today.

Antibody prevalence surveys have also been carried out in areas where typhoid is highly endemic. Seroepidemiological studies in Peru and Chile performed in the 1970s showed that by 15–19 years of age, 50–80% of teenagers had serological evidence of past infection with *S.* Typhi.[43,44]

5.2. Epidemic Behavior and Contagiousness

In the United States, scattered outbreaks of typhoid fever occur when a carrier contaminates food or a water supply.[24,25,29] The epidemic that occurred in Dade County, Florida illustrates how a segment of our society may become infected when sewage disposal and water supply are improperly controlled.[29] The critical epidemiological link in this outbreak was thought to be a mentally retarded child who acquired the infection from an asymptomatic carrier living in a neighboring house. It is believed that this child subsequently contaminated the flawed water supply in the migrant labor camp, resulting in 222 cases in the camp population, 184 of whom were hospitalized. This was the largest single outbreak in the past half century. Other large epidemics in industrialized countries have occurred in the past five decades in Scotland (504 cases)[102] and Zermatt, Switzerland (280 cases).[103] In Scotland, the source of the infection was canned corned beef shipped from Argentina. The meat per se did not contain typhoid bacilli prior to processing (raw meat has never been found to be contaminated with this organism, attesting to the unique adaptation of typhoid bacilli to humans). However, after the canning process, the cans were heat sterilized and then placed in contaminated river water to cool. As the cans cooled, water was drawn into the cans through minute leaks in the seams. Those who handled the meat from the cans became potential cases as well as possible disseminators of the bacteria. Furthermore, when the meat was cut by machines, the blades became contaminated, and other meats subsequently cut on these machines

also acquired typhoid bacilli, which was then spread to other consumers.[102]

The epidemic in Zermatt occurred from contamination of the town water supply. The contamination lasted for at least 1 month before the epidemic was recognized and chlorination and other measures could be instituted to treat the water.

Another large epidemic of interest was caused by chloramphenicol-resistant *S.* Typhi in Mexico City from 1972 to 1974.[88] At the time typhoid was endemic in that city, but the marked increase in number of typhoid fever cases admitted to hospitals quickly focused attention on the fact that this new strain was responsible for two thirds of the increased incidence. An epidemiological investigation suggested that the strain may have been disseminated by soft drink vehicles made with contaminated water.[104] The Mexican strain was found to be responsible for typhoid fever in Switzerland, the United Kingdom, the United States, and other parts of the world. Travelers to Mexico acquired the disease and brought it back to this country and the others. In Los Angeles in 1972, the incidence of the disease doubled, due mainly to imported cases from Mexico.[105] Fortunately, very few secondary cases of typhoid fever occurred in this country as a result of the importation of the antibiotic-resistant Mexican strain.

One other water source of infection that has been documented involves oysters harvested from polluted water; typhoid and other enteric pathogens can be concentrated from the water strained by the bivalves.[106] In situations where latrines are not fly-proofed or exposed human feces is common, flies have been shown to transmit typhoid bacilli by contamination of their feet as they feed on feces and subsequent carrying of the organisms to food.[107]

Typhoid fever is essentially spread only by consumption of contaminated food or water vehicles. Under rare circumstances, direct person-to-person transmission through anal–oral spread may occur, as among homosexuals who indulge in anolingual sexual practices.[108,109]

Transmission occurs among clinical microbiologists in hospital diagnostic bacteriology laboratories.[6,7] The handling of specimens containing *S.* Typhi has caused numerous cases of typhoid fever. Twenty-five cases of laboratory-acquired typhoid fever were reported to the CDC from 1977 to 1979, among which 14 were related to a proficiency-testing program. These data indicate the need for a good training program in order to upgrade the skills and techniques of microbiology technicians. The organism can be handled safely in hospital diagnostic laboratories, but great care must be taken to avoid contaminating fingers, pens, pencils, and laboratory paraphernalia, since these may serve as fomites to transmit the bacteria to the mouth. In some instances, it is believed that aerosols may be involved in the transmission of *S.* Typhi within clinical microbiology laboratories, not by direct inhalation but by contamination of nearby surfaces and objects that subsequently serve as fomites. Aerosols may be created as culture tubes containing *S.* Typhi are opened, leading to contamination of nearby objects, which subsequently contaminate hands. If hands are not adequately washed, they can carry the organisms to food or directly to the mouth. Small numbers of volunteers exposed to small-particle aerosols containing 10^5 typhoid bacilli failed to develop signs of infection. This dose given by mouth caused disease in about 38% of volunteers; thus, the respiratory tract appears to be a less effective route of inoculation than the gastrointestinal tract.

Typhoid fever has a relatively low risk of contagion. Person-to-person transmission can occur by anal–oral spread such as changing the soiled bed linens of an undiagnosed patient. Patients with typhoid fever shed the etiologic agent from the gut and urinary tract. Aerosol dissemination from these sources would appear to be highly unlikely.

5.3. Geographic Distribution

In less-developed areas of the world where fecal contamination of water and food is common, incidence rates of many enteric infections are high, including typhoid fever. Typhoid fever remains common in South, Southeast, and Central Asia, much of sub-Sahara Africa, the Philippines, Haiti, some regions of Central and South America, a few Eastern European countries, and parts of the Middle East.

Transmission of *S.* Typhi is favored wherever sanitation is primitive such that human fecal waste can contaminate untreated water sources that are widely consumed. Additional transmission of a more sporadic nature is favored where hygiene practices are primitive and chronic or short-term carriers can contaminate food. However, typhoid and paratyphoid fever are not common in every less-developed region. Rather, the prevalence of the disease is spotty and requires the presence of the human reservoir as well as the means for transmission. In most areas of the world where *S.* Typhi is prevalent the syndrome of classical clinical typhoid fever is most often observed in school-age children and young adults. In some densely populated urban slums the peak incidence of clinical typhoid is seen in preschoolchildren. In general overt typhoid fever is uncommon in infants less than 12 months of age (although some severe cases are occasionally seen in this age group).

In the latter half of the nineteenth century, high incidence rates of typhoid fever were observed in most of the major cities of Europe and North America. Transmission

of typhoid in these cities was amplified as untreated water from nearby rivers that had heavy fecal contamination was an important source of municipal drinking water for inhabitants of the cities. Treatment of the water sources led to striking decreases in the transmission of typhoid, reflected by plummeting incidence rates.[16,17] Typhoid fever is still common in a number of large cities in the less-developed world where segments of the population are not served by piped, treated, monitored water supplies. These cities include Cairo, Egypt; Jakarta, Indonesia; Bombay, New Delhi, and Kolkata, India; Dhaka, Bangladesh; Dushanbe, Tajikistan; and Karachi and Lahore, Pakistan.

In some large cities, endemic typhoid persisted despite provision of virtually all of the population with treated water. In such exceptions, another form of amplification was responsible. One example was Santiago, Chile in the 1970s and 1980s, where typhoid remained notably endemic despite 96% of the population having access to treated, bacteriologically monitored water.[44,110] Irrigation of crops of salad vegetables such as lettuce, celery, and cabbage during summer with untreated sewage was epidemiologically linked as the amplification event.[111,112] Abrupt discontinuation of this practice following a small outbreak of cholera in 1991 led to a precipitous decline in the incidence of typhoid fever and its virtual disappearance as a public health problem in an infamous endemic area where a few years earlier the WHO sponsored four successive large-scale field trials of efficacy of typhoid vaccines.[47–49,113,114]

5.4. Temporal Distribution

In endemic areas, typhoid typically exhibits seasonality but the peak season differs based on a number of epidemiologic features that affect transmission and survival of *S.* Typhi. In temperate and sub-tropical areas where typhoid remains endemic, most cases occur during the summer months. The cases acquired by US tourists usually occur in the summer, coinciding with the peak travel time. The remaining cases appear sporadically during the year. In many endemic areas, typhoid typically shows a highly seasonal pattern. In Chile, Ecuador, and Peru there was a clear-cut peak in summer,[110] while in Northern Nigeria[115,116] typhoid peaks during the dry season.

5.5. Age

Perhaps the most striking and fascinating epidemiological feature of typhoid fever in endemic areas is its age-specific incidence pattern. The classical age-specific epidemiologic pattern that has been described for decades from many disparate endemic areas is one in which the incidence of typhoid is low in the first year of life, begins to be seen in pre-schoolchildren, peaks in school-age children, remains high in young adults, and then falls again in middle age (Table 3). These age-specific incidence data were based on passive surveillance methods in which cases were identified among cases who felt ill enough to seek health care.[44,110,117,118] More recent passive surveillance studies from South Asia[37] and Southeast Asia[35] and Central Africa[36] based on detection of cases who seek health care have revealed similar age-specific incidence patterns in which the peak incidence of bacteriologically confirmed typhoid fever occurs in school-age children (Table 1).

In the early 1990s, Mahle and Levine[56] reviewed the validity of the dogma that typhoid fever is relatively rare in infants, toddlers, and pre-schoolchildren based on data available at that time. Notification data and hospital-based reports that they reviewed supported the classical teaching, demonstrating a much lower incidence in the 0- to 4-year-old age group than in school-age children (5- to 19-year-olds).

Table 3. The Mean Annual Age-Specific Incidence of Typhoid Fever per 100,000 Population, Based on Notification Data in Diverse Geographic Regions and Time Periods

Age group (years)	Palestine Mandate 1934–1942[118]	British Guiana 1956–1960[117]	Peru 1971[56]	Santiago, Chile 1977–1981[44]
0–4	127	48	67	89
5–9	307	180[a]	114	272
10–14	266	180[a]	144	333
15–19	236	112[a]	129	283
20–24	271	112[a]	102[a]	247
25–29	196	66[a]	102[a]	153[a]
30–34	108[b]	66[a]	50[c]	153[a]

[a]Incidence reported for cohorts spanning 10 years.
[b]Incidence of 30- to 39-year age group.
[c]Incidence of population >30 years of age.

Importantly, they examined age-specific incidence rates in a series of waterborne outbreaks and found a similar age distribution as was observed in endemic disease, suggesting that the lower morbidity in younger children is not due to decreased exposure to *S.* Typhi but rather to host factors. Mahle and Levine concluded that following exposure and infection most very young children (< age 2 years) appear to develop a mild form of clinical illness that is not readily recognized as typhoid fever. This conclusion was supported by systematic blood culture studies in typhoid-endemic areas among febrile children who were brought to health centers. *S.* Typhi bacteremia was documented in infants and toddlers < 24 months of age but they clinically manifested only mild febrile illness that was most often diagnosed as a "viral syndrome".[31] Young children with typhoid also exhibit less prominent pathology of the small intestine.[31] Together, these features suggest that young children readily become infected with *S.* Typhi, but that a distinct pathogenesis usually produces a remarkably mild illness.

However, a fresh look at the question of the age-specific incidence pattern of endemic typhoid fever has resulted from several studies carried out in South Asia since the mid-1990s that utilized active surveillance. The active surveillance methods involved house to house visits once or twice weekly to detect cases of fever among household members followed by the collection of blood cultures from the febrile subjects.[32,34] Whereas these studies have corroborated that typhoid fever is rare in infants < 12 months of age, these active surveillance studies revealed a high incidence of *S.* Typhi bacteremia in toddlers and pre-schoolchildren, 12–59 months of age.[32,34]

Older adults in endemic areas appear to be relatively immune, presumably because of frequent boostering of immunity acquired earlier. In the United States, those most likely to acquire the disease at home are adults under age 30.[93,94] Three fourths of 857 patients reported between 1975 and 1984 were in this age range. Median age was 20.[93] The travel-associated cases had a median age of 23 years. Persons of these ages had no background immunity, having been born and raised in a country where the disease is no longer prevalent ($\sim$1 case/10^5 annually since 1970 compared to $\sim$10 cases/10^5 in 1955 and about 30 cases/10^5 in 1945). Vaccine-induced immunity, including that conferred by the more recent Ty21a and Vi vaccines, is less effective in young children, presumably because of a lack of background immunity.

While the median age of persons with typhoid fever was 22–24 years in the period 1984–1986 in the United States, the median age of carriers in those years was 71, 58, and 69 years, respectively. In endemic areas, the prevalence of carriers steadily increases with age.

5.6. Sex

There is no prominent effect of sex on the incidence of acute typhoid fever; both sexes are equally susceptible. However, the prevalence of chronic carriers is threefold greater in females.[99,100] This is because the propensity to become a chronic carrier following acute typhoid infection, either symptomatic or subclinical, is related to the presence of preexistent gallbladder disease. Infection of the biliary tree and the gallbladder is universal during acute typhoid fever. Indeed, culture of bile-stained duodenal fluid specimens is one of the highest yield clinical bacteriological procedures to isolate *S.* Typhi during acute typhoid fever.[60] Just as the prevalence of cholelithiasis and chronic gallbladder disease occurs with greater frequency in females and increases with age, so too an identical prevalence pattern of chronic biliary typhoid carriers is observed in endemic areas.[100]

5.7. Race

There are no data to support racial susceptibility to typhoid fever. While many series in the US literature indicate that more blacks have typhoid fever, it is probable that the living conditions, e.g., poor sanitary conditions, are the precipitating factor, not race. In volunteer studies, no evidence of race-associated susceptibility was detected. An unusually virulent form of clinical typhoid fever used to be encountered with frequency in Jakarta, Indonesia, where obtundation and shock were common.[61,119] The case fatality ratio in such severely ill patients was about 50% unless steroids were coadministered with appropriate antibiotics. However, it remained around 10% among the most ill hospitalized patients, even with adjunct steroid therapy.[119] Multiple hypotheses have been put forth to explain this severe form of typhoid fever, which is concentrated on the island of Java. One hypothesis proposes that the genetic makeup of the Javanese population predisposes them to respond to typhoid infection with a particularly severe clinical syndrome. Indeed, recent reports that describe enhanced susceptibility and resistance to typhoid fever in Vietnamese subjects based on certain genotypes give credence to the role of genetics in influencing risk of developing clinical typhoid fever following exposure and the severity of disease.[121–123]

5.8. Occupation

Several occupations have historically been associated with an increased risk for acquiring typhoid fever. These include sewer workers, soldiers,[124,125] and most recently, clinical microbiologists.[6,7] Clinical microbiologists are now

recognized as one high-risk US population for which immunization with one of the new vaccines is indicated.

5.9. Occurrence in Different Settings

In industrialized countries, a large proportion of sporadic cases occur among travelers (Table 2).[5,126–130] When outbreaks occur in the United States and other industrialized countries that have high levels of sanitation, controlled water supplies, and sophisticated food hygiene practices, a careful epidemiological investigation almost always incriminates the food or water vehicle responsible for the outbreak and often identifies a chronic carrier responsible for its contamination.[24,25,29] Similarly, epidemiological investigation of sporadic, non-travel-associated cases in the United States also often identifies a chronic carrier, such as an elderly family member, who serves as the reservoir of infection.[131]

In contrast, in typhoid-endemic areas in less-developed countries, where populations live in underprivileged conditions without controlled, piped water supplies, means to remove human waste, refrigeration for preserving food, or adequate food hygiene practices, it is usually exceedingly difficult to identify the specific vehicles of transmission of sporadic cases or the human reservoir.[132–136]

5.10. Socioeconomic Factors

Wherever inadequate sanitary facilities exist and water supplies are subject to fecal contamination, the opportunity exists for enhanced transmission of all enteric infections, but especially typhoid fever. The unique adaptation of *S.* Typhi to humans and the survival characteristics of this organism make it a particular threat to spread in populations living under substandard sanitary conditions. Prior to the availability of treated water and sewer systems, all strata of society were at risk. Endemic regions continue to exist in the world primarily because the poorer segments of the population in those areas remain underserved by adequate water supply and sanitation services and lack of detection and restriction of carriers. Provision of means to remove human waste and of treated, bacteriologically monitored water precludes widespread transmission and virtually eliminates typhoid fever from previously endemic loci.

5.11. Other Factors

There is no reliable evidence indicating increased or decreased susceptibility of patients with malnutrition to typhoid fever. The untreated disease causes a severe metabolic drain, so illness in a host with undernutrition will create a double hazard. Patients with various parasitic infections such as roundworms or schistosomes are readily infected with *S.* Typhi. In the first instance, typhoid fever in the host will cause the roundworms to migrate out through the mouth and anus. Reasons for this exodus from the gut are unknown. Schistosomiasis causes tissue scarring and obstruction, especially in the genitourinary tract by *Schistosoma haematobium*, and *S.* Typhi can remain indefinitely in the scar tissue or adherent to the trematode itself.[137] Salmonellae express fimbriae that allow adherence to the glycolipids on the surface of the worm.[137] A common consequence of such symbiotic coinfection is recurrent silent *S.* Typhi bacteremia in the host without any clinical evidence of typhoid fever.

6. Mechanisms and Routes of Transmission

Typhoid bacilli enter the host by the oral route via ingestion of contaminated food or water. The disease has been shown to be one of several enteric infections that can be sexually transmitted by anolingual sexual practices.[108,109] Flies can carry *S.* Typhi on their feet and have been incriminated, indirectly, as mechanical vectors that contaminate food.[107] Rarely, infection is believed to have been acquired by aerosol.

It is helpful to consider that typhoid fever is transmitted by the fecal–oral route in two broad manners: a "short cycle" and a "long cycle." The short cycle is typified by an individual carrier who contaminates food vehicles that are consumed by family members, or by participants at a communal gathering (wedding, party, etc.), or by a chronic carrier food working as a food handler in a restaurant.[24] Thus, it is a short distance from point of contamination to consumption of the vehicle by the susceptibles. In contrast, examples of long-cycle infection include contamination of water supplies by sewage,[26] contamination of piped water supplies that are distributed,[26,138] and finally widespread dissemination of typhoid bacilli via contaminated foods that may be transported over long distances.[102]

Examples of short-cycle sporadic cases and outbreaks include the families served by the infamous cook, "Typhoid Mary,"[139] and restaurant outbreaks in Texas,[140] Maryland,[24] and New York.[141] Most outbreaks in the United States are related to the short-cycle mode of transmission.[24,91,141]

The long-cycle transmission is exemplified by the Aberdeen[102] and Zermatt[103] epidemics of the 1960s and the Northern Israel outbreak in the late 1980s.[142] The Aberdeen epidemic was caused by consumption of contaminated tins of corned beef canned in Argentina and shipped

to Scotland. The Zermatt epidemic was caused by a carrier contaminating a mountain stream at the point where it served as the intake for the water supply of Zermatt.

7. Pathogenesis and Immunity

7.1. Pathogenesis

S. Typhi and *S.* Paratyphi A and B are highly invasive bacteria that rapidly and efficiently pass through the intestinal mucosa of humans to eventually reach the reticuloendothelial system, where, after a 8- to 14-day incubation period, they precipitate a systemic illness. *S.* Typhi is a highly host-adapted pathogen; humans comprise the only natural host and reservoir of this infection. Our comprehension of the steps involved in the pathogenesis of typhoid fever comes from four sources: (1) clinicopathological observations in humans[143]; (2) volunteer studies[45]; (3) studies of a chimpanzee model[144]; and (4) analogies drawn from *S.* Typhimurium and *S.* Enteriditis infection in mice – the "mouse typhoid" model.[145] The probable steps in the pathogenesis of *S.* Typhi infection in humans are summarized below.

Susceptible human hosts ingest the causative organisms in contaminated food and water. The inoculum size and the type of vehicle in which it is ingested greatly influence the attack rate for typhoid fever and also affect the incubation period, a relationship that was documented in volunteer studies in the 1960s (Table 4). Doses of 10^9 and 10^8 pathogenic *S.* Typhi ingested by volunteers in 45 ml of skim milk induced clinical illness in 98% and 89% of individuals, respectively; doses of 10^5 caused typhoid fever in 28–55% of volunteers, whereas none of 14 subjects who ingested 10^3 organisms developed clinical illness.[45]

In the fasting normochlorhydric stomach, gastric acid undoubtedly inactivates many of the typhoid bacilli that are ingested. However, some foods may serve as a buffer to diminish this otherwise formidable protective acid barrier. After passing through the pylorus and reaching the small intestine, the bacilli rapidly penetrate the mucosa by one of two mechanisms to arrive in the lamina propria. One mechanism involves uptake of the bacilli into endocytic vacuoles and their passage through the enterocytes to be ultimately released into the lamina propria without destroying the enterocyte.[146] In the second, quite distinct, invasive mechanism, typhoid bacilli are actively taken up by M cells,[147] the domelike epithelial cells that cover Peyer's patches and other organized lymphoid tissue of the gut. From here they enter the underlying lymphoid cells. In yet a third mode of entry, it has been proposed that *Salmonella* may sometimes take a paracellular route between enterocytes.[148]

Upon reaching the lamina propria in the nonimmune host, typhoid bacilli elicit an influx of macrophages and dendritic cells that ingest the organisms but are generally unable to kill them. Some bacilli apparently remain within macrophages of the small intestinal lymphoid tissue. Other typhoid bacilli are drained into mesenteric lymph nodes where further multiplication and ingestion by macrophages take place. Eventually, there is a release of tumor necrosis factor-alpha, interleukin-2 (IL-2), IL-6, and other inflammatory cytokines by the macrophages (and perhaps by enterocytes).

Postmortem studies have documented the marked inflammatory responses that occur in the distal ileum in the Peyer's patches and other organized lymphoid aggregations. Presumably, cytokine release elicited by the intracellular *S.* Typhi is responsible for these cellular changes. It is from these lesions in the distal ileum and ascending colon that hemorrhage can occur later in the disease course. Gross bleeding comes from eroded vessels in or near the Peyer's patches. This complication occurs late in the second week in about 1–3% of untreated patients and rarely in patients whose treatment with an appropriate antibiotic is begun late in their clinical course. Perforations of the bowel wall occur in the same sections of the gut as the hemorrhages.

Shortly after invasion of the intestinal mucosa, a primary bacteremia is believed to take place in which *S.* Typhi are filtered from the circulation by fixed phagocytic cells of the reticuloendothelial system. The main route by which typhoid bacilli reach the bloodstream in this early stage is by lymph drainage from mesenteric nodes entering the thoracic duct and then the general circulation. Conceivably, ingestion of a massive inoculum followed by widespread invasion of the intestinal mucosa could result in rapid and direct invasion of the bloodstream. As a result of this primary bacteremia, the pathogen rapidly attains an intracellular haven throughout the organs of the reticuloendothelial system where it resides during the incubation period (usually 8–14 days) until the onset of clinical typhoid fever. Clinical illness is

Table 4. Incubation Periods of Typhoid Fever Related to Size of Infecting Dose[a]

Dose[b]	Attack rate (%)	Mean incubation period (days)
10^3	0	–
10^5	38	13
10^7	50	11
10^9	90	5.8

accompanied by a fairly sustained, albeit low level (1–10 organisms/ml), "secondary" bacteremia.

The Vi antigen is a virulence property and in most endemic areas and outbreaks virtually all strains freshly isolated from patients possess this polysaccharide capsule.[81] Both epidemiological observations and studies in volunteers support the contention that *S.* Typhi strains that possess Vi are more virulent than strains lacking this polysaccharide.[45]

The bacteremia of typhoid fever will persist for several weeks if antibiotic therapy is not given, and the blood may be seeded from the liver as well as the lesions in the intestinal tract. The symptoms and signs of typhoid fever are not believed be due to circulating endotoxin. Most patients have no serum endotoxin detected by the limulus assay.[149] However, in patients who present with septic shock syndrome, circulating endotoxin can be demonstrated.[119] These patients have a higher mortality rate and require a combination therapy of steroids and antibiotics.[119]

Relapses were observed in about 8% of patients suffering from typhoid fever in the preantibiotic era. The rate in patients treated with the first (chloramphenicol) and second (ampicillin, amoxicillin, and trimethoprim/sulfamethoxazole) generation of antibiotics used for therapy of typhoid ranged from 10 to 35%. The organisms that initiate relapse appear to come from within the reticuloendothelial system. Typhoid bacilli can be isolated from liver biopsies during the relapse, and also from bone marrow many months after the patient has fully recovered from the symptoms. Relapses usually occur about 3 weeks after the last febrile day or about 2 weeks after cessation of antibiotics. Most relapses are milder than the initial illness, last for only a few days, and respond promptly to appropriate antibiotic therapy. Relapse after treatment with oral fluoroquinolones and azithromycin and after parenteral ceftriaxone therapy is distinctly uncommon.

During the primary bacteremia that follows ingestion of typhoid bacilli and seeds the reticuloendothelial system, organisms also reach the gallbladder, an organ for which *S.* Typhi has a remarkable predilection.[144,150] *S.* Typhi can be readily cultured from bile or from bile-stained duodenal fluid in patients with acute typhoid fever.[60,61,120] In approximately 2–5% of patients, the gallbladder infection becomes chronic.[99] The propensity to become a chronic carrier is greater in females and increases with age at the time of acute *S.* Typhi infection, thereby resembling the epidemiology of gallbladder disease.[99,101] The infection tends to become chronic in those individuals who have preexistent gallbladder pathology at the time of acute *S.* Typhi infection. Carriers shed as many as 10^9 organisms/g feces.[151] These organisms are propelled the length of the gastrointestinal tract without penetrating and causing disease in the host.

7.2. Immunity

Age-specific incidence patterns suggest that repeated exposure in endemic areas results in the acquisition of immunity. Moreover, it is well recognized that chronic carriers do not themselves develop clinical typhoid fever, despite having hundreds of billions of virulent typhoid bacilli pass the length of their intestine each day. On the other hand, natural infection-derived protective immunity is not absolute. In volunteer rechallenge studies, an initial clinical typhoid infection conferred only 30% protection against subsequent challenge with the homologous *S.* Typhi strain.[152] Similarly, repetitive clinical infections have been recorded in closed populations that experienced multiple sequential outbreaks of typhoid fever.[124]

A broad immune response is evident following wild-type typhoid infection, with the appearance of serum antibodies, mucosal SIgA responses, an array of cell-mediated immune responses, and a form of antibody-dependent cellular killing of *S.* Typhi. The licensed parenteral purified Vi polysaccharide and attenuated Ty21a live oral vaccines each elicit widely divergent immune responses, yet in its own way each confers significant protection. This suggests that several of the immune responses elicited by wild-type infection or by an array of vaccines can each individually mediate protection.

8. Patterns of Host Response

There is a wide spectrum of clinical syndromes associated with infection by *S.* Typhi.[1,2,31,56,153] Many persons exposed to small numbers of bacteria will be asymptomatic and probably will show no clinical signs of infection.[45] A small percentage of infected individuals develop bacteremia but are symptoms free.[154] Perhaps it is from this population that many carriers have developed, as many carriers do not recall having had the disease. The majority of patients with clinically overt disease have a relatively uniform course. A proportion of patients develop severe or complicated disease. In part, the duration of untreated disease prior to initiation of therapy influences the severity of the clinical disease. The curious, severe, clinical form of typhoid fever that was in the past commonly encountered in Jakarta, Indonesia has already been described,[119] as has the atypical generally mild presentation of *S.* Typhi infection observed in infants and toddlers.[31,56]

8.1. Clinical Features

The major signs and symptoms of typhoid fever are relatively nonspecific.[2] There is fever and an associated

moderately severe generalized headache. The temperature increases in a stepwise fashion over the course of 2–3 days, reaching a peak of 103–104°F. During this time, the patient also complains of abdominal pain and may either have diarrhea or (in adults and older children) be constipated. Examination of the abdomen will reveal palpation tenderness in the lower quadrants. Often, one can palpate dilated loops of bowel and sense the displacement of air and fluid under the probing fingers. This indicates that an ileus is present, a probable consequence of the inflammatory process occurring in the lamina propria and Peyer's patches. Late in the first week, careful inspection of the skin may reveal a few rose spots. These are slightly raised erythematous, nontender lesions found in light-skinned persons in the anterior chest or abdominal areas. They initially blanch with pressure but may gradually become fixed as small cutaneous hemorrhages. These lesions are caused by *S.* Typhi organisms infiltrating the endothelial cells of skin capillaries and inducing a perivascular infiltrate and subsequent leaking of blood. Culturing a skin snip of fresh rose spots will yield the organism.[59]

The course of the disease in untreated patients is characterized by a continuous fever with a relative bradycardia in adults. The continuous fever will persist for 2 weeks or longer if no antibiotic is given, and defervescence occurs slowly over the ensuing 2–3 weeks. Such patients have a prolonged convalescence (3–4 months) because of the severe negative nitrogen balance that is a consequence of the prolonged infection. Patients who are receiving an appropriate antibiotic will respond with a gradual reduction in the fever over a 3- to 4-day period.

Complications are the significant prognostic indicators.[1,2] Gastrointestinal hemorrhage or perforation is responsible for many of the fatalities with this disease. Both these events occur after about 2 weeks of untreated disease. The signs and symptoms of a perforated loop of intestine present as an acute abdominal crisis.

8.2. Diagnosis

The diagnosis should be suspected in any patient with fever, abdominal pain, constipation, and headache. A prior history of travel to an endemic area will be an alerting epidemiological fact that should be followed up by appropriate blood and stool cultures. Because of the long incubation (which can be 2 weeks or longer), a thorough epidemiological history should be taken, since the patient may be the index case of a local outbreak. It is important to notify local health authorities promptly.

Typhoid bacilli appear in the blood with the onset of fever, and in untreated patients bacteremia remains for about 2 weeks before abating. The number of organisms in the blood is low, usually less than 10/ml cultured blood. The bacteriological diagnosis is confirmed by positive blood cultures in only about 50–75% of patients. Variables such as prior antibiotic therapy, the volume of blood cultured (the larger the volume, the better), the type of broth used (it should contain an anticomplementary agent), and the number of days that cultures are incubated, all impact on whether a patient with typhoid fever will have a positive blood culture. Diagnosis is confirmed in the remaining patients by bone marrow, bile-stained duodenal string, stool, or rose spot cultures. Stool cultures become positive shortly after ingestion of the organism and may become negative with onset of disease, but may again yield the organism by the end of the first week of disease. Without therapy, stools may readily remain positive for *S.* Typhi for as long as 4 months; beyond this period, continued presence indicates a greater than 90% chance of being a permanent carrier. Antibiotic treatment may cause temporary suppression of the isolation of typhoid bacilli from stools during the therapy.

Antibodies to O and H antigens are already present during the first week of illness.[43] In some of the volunteers with induced disease during studies carried out in the 1960s and early 1970s, the baseline titers prior to challenge with virulent *S.* Typhi were undetectable or low, e.g., 1:20 or 1:40 for O antibodies, yet no rise in titer occurred during the entire time of the prolonged follow-up.[45] These men also had bacteremia and positive stool cultures, an obvious source of antigens.

The differential diagnosis will include other infectious agents that may cause an enteric-fever-like syndrome such as tularemia and other salmonellae. Brucellosis, infectious mononucleosis, dengue fever, and infectious hepatitis may initially be confused because of similar symptoms associated with these febrile illnesses. Leptospirosis may occur with significant abdominal findings and mimic typhoid.

9. Control and Prevention

9.1. General Concepts

Control of typhoid fever requires the identification and tracking of carriers, control of their occupational activities, and, most important, provision of safe water supplies and human waste removal systems. All patients with the disease must be reported to the local health department. Patients should be nursed using enteric precautions. Linen soiled by feces should be handled with disposable gloves and hands should be scrupulously washed following contact with the patient.

Carriers, when discovered, are frequently elderly females. Since the current highly effective treatment regimen

(for susceptible strains) consists of up to 4 weeks of oral ciprofloxacin or norfloxacin,[155,156] care and encouragement must be provided to these elderly individuals during the therapy. If adverse reactions preclude administration of the full course, it is heartening to recognize that even short courses of 10–14 days have succeeded in eradicating the chronic carrier state in certain individuals.[155]

The stringency with which local health departments maintain surveillance of chronic carriers varies greatly. In some areas, these patients are required to submit stool specimens once or twice a year to confirm the continued presence of *S.* Typhi; in other areas, only a listing is maintained. Carriers are prevented from working in any position that could result in their contaminating food or drinking water. This type of control is lacking in most endemic areas, and hence typhoid fever can remain as a common disease.

9.2. Antibiotic and Chemotherapeutic Approaches to Prophylaxis

There is no evidence to support the usefulness of prophylactic antibiotic treatment in preventing disease. To the contrary, data exist that suggest that administration of antibiotics following ingestion of typhoid bacilli but before the onset of clinical illness would not be effective. In tissue cultures, typhoid bacilli persist in the intracellular environment for at least 21 days, despite adequate concentrations of antibiotics in the solution bathing the cells. In the volunteer challenge studies carried out by Hornick et al.[45] four men were begun on chloramphenicol treatment 24 hours after ingesting the 90% infective dose (ID_{90}) of *S.* Typhi. In the two who took the antibiotic for 6 days, the incubation period was delayed by that same period compared to controls. In two men who were maintained on chloramphenicol for 28 days, no disease developed, but there were signs of infection such as positive stool cultures and antibody titer rises.

There is no justification for employing prophylactic antibiotics to prevent typhoid fever. The variable attack rate after known exposure makes it impractical to attempt prophylaxis. If a known common source exposure has occurred, it is much more prudent to maintain surveillance of the potential patients and to treat at the first signs of illness, after obtaining blood and stool cultures. Under these circumstances, treatment with effective antibiotics will reduce the duration and severity of the disease and will prevent complications by limiting the progression of the disease.

9.3. Immunization

The venerable inactivated whole cell parenteral vaccines, including heat-inactivated, phenol-preserved vaccine and acetone-inactivated vaccine, conferred moderate levels of protection for up to 7 years.[18–21,157] However, they were distinctly unsatisfactory vaccines because they caused adverse reactions at such high frequency. In controlled trials, approximately 25% of recipients of the inactivated whole cell vaccines developed fever and systemic reactions and about 15% had to miss work or school.[20,23] For this reason, these vaccines are no longer being manufactured and have been replaced by two modern licensed vaccines: live oral vaccine strain Ty21a (Vivotif) and parenteral purified Vi capsular polysaccharide vaccine (TyphiViM).[3] Both these vaccines confer comparable protection and are well tolerated.

9.3.1. Ty21a. Ty21a, an attenuated strain of *S.* Typhi that is safe and protective as a live oral vaccine, was developed in the early 1970s by chemical mutagenesis of a pathogenic *S.* Typhi strain Ty2.[158] The characteristic mutations in this strain include an inactivation of the *ga*lE gene that encodes an enzyme involved in LPS synthesis and the inability to express Vi polysaccharide. However, approximately two dozen additional mutations are also present in Ty21a. Although Ty21a has proven to be remarkably well tolerated in placebo-controlled clinical trials,[3] it is not clear precisely what mutations in fact are responsible for the stable, impressive attenuation of this vaccine.

Ty21a provides significant protection without causing adverse reactions. Results of multiple double-blind, placebo-controlled studies that utilized active surveillance methods to assess the reactogenicity of Ty21a in adults and children showed that adverse reactions were not observed significantly more often in the vaccine recipients than the placebo group for any symptom or sign. In large-scale efficacy field trials with Ty21a, involving approximately 465,000 schoolchildren in Chile and 32,000 in Egypt, and approximately 20,000 subjects from 3 years of age to adulthood in Indonesia, passive surveillance failed to identify vaccine-attributable adverse reactions or other safety issues.[47–49,52,157,159]

Controlled field trials of Ty21a emphasize that the formulation of the vaccine, the number of doses administered, and the spacing of the doses markedly influence the level of protection that can be achieved.[47–49,52,113,160] Two formulations, including enteric-coated capsules and a "liquid" formulation in which lyophilized vaccine is reconstituted along with buffer powder into a vaccine cocktail, are licensed; however, in recent years only the enteric-coated capsule formulation has been manufactured. Based on a field trial in Chile that demonstrated that three doses of Ty21a in enteric-coated capsules given on an every other day schedule for three dosings conferred 67% efficacy over 3 years of follow-up and 62% protection over 7 years of follow-up,[47,114] this formulation and schedule are used throughout the world except for

Table 5. A Comparison of the Efficacy of Two, Three, or Four Doses of Ty21a Vaccine in Enteric-Coated Capsule Formulation. Results of a Large-Scale, Randomized, Field Trial in Area Sur and Area Central of the Metropolitan Region of Santiago, Chile[a]

Surveillance from 11/84 to 10/87	Two doses	Three doses	Four doses
No. of vaccines	66,615	64,783	58,421
Cases of bacteriologically confirmed typhoid fever	123	104	56
Incidence/10^5	184.6[b]	160.5[c]	95.8[d]
95% confidence interval	152–271	130–191	71–121

North America. The United States and Canada recommend a four-dose regimen with an interval of 48 hours between doses. This was based on results of a large-scale, randomized comparative trial carried out in Santiago, Chile wherein four doses of Ty21a in enteric-coated capsules given within 8 days were shown to be significantly more protective than two or three doses (Table 5).[113]

In the mid-1980s, the Swiss Serum and Vaccine Institute (currently BernaBiotech, a Crucell Company) succeeded in preparing a "liquid suspension" formulation of Ty21a for large-scale field trials that was amenable to large-scale manufacture. The new formulation consisted of two packets, one containing a dose of lyophilized vaccine and the other containing buffer. Contents of the two packets are mixed in a cup containing 100 ml of water and the suspension is then ingested by the subject to be vaccinated. Randomized placebo-controlled field trial were carried out in Santiago, Chile[48] and Plaju, Indonesia[52] to compare directly this new liquid formulation of Ty21a (that somewhat resembles what was used in the Alexandria, Egypt field trial[160]) with the enteric-coated capsule formulation. In both trials the vaccine administered as a liquid suspension was superior to the vaccine in enteric-coated capsules. In the Santiago trial over 3 years of follow-up the liquid suspension formulation conferred 77% efficacy [95% confidence interval (CI), 60–87%], whereas in Indonesia the liquid formulation conferred 53% efficacy (95% CI, 35–66%) Over two additional years of follow-up in the Santiago trial (total 5 years), the liquid formulation conferred 78% efficacy. Ty21a given as a liquid suspension protected young children as well as older children. In previous trials with enteric-coated vaccine, young children were not as well protected as older children.[47]

9.3.2. Vi Polysaccharide Vaccine. In the 1970s and early 1980s, methods were developed to purify Vi capsular polysaccharide so that it was 99.8% free of contaminating LPS and was not denatured.[50,51,81,161,162] This was an important breakthrough because as little as 5% impurity with LPS can result in systemic adverse reactions in a few percent of recipients.[162] In contrast, when Vi vaccine is highly purified, it is well tolerated and febrile reactions are observed in only 1–2% of subjects. In clinical trials, well-tolerated 25 and 50 μg single parenteral doses of purified Vi stimulated rises of serum Vi antibodies in the vast majority of vaccinated adults and school-age children.[50,51,162] Administration of subsequent parenteral doses did not achieve boosts in antibody;[163] thus, the Vi polysaccharide functions like a T-cell-independent antigen. Nevertheless, the antibodies elicited by a single dose persisted for at least 3 years.[164] Passive surveillance carried out during field trials showed the Vi vaccine to be as well tolerated as the licensed (meningococcal and pneumococcal) polysaccharide vaccines that served as the control preparations in these trials.[50,51]

Two randomized, controlled, double-blind field trials were carried out in Nepal and South Africa to assess the efficacy of a single 25 μg dose of nondenatured purified Vi vaccine. Over 17 months of surveillance in Nepal, the vaccine conferred 72% vaccine efficacy.[51] In South Africa, the vaccine provided 64% protection over 21 months of follow-up and 55% protection over 3 years.[50] The Nepal trial included all ages from pre-school to adulthood, whereas the South African trial was performed in schoolchildren. A third controlled field trial was carried out in subjects 3–50 years of age in Guangxi, China that evaluated the protective efficacy of a single 30 μg dose of a Vi polysaccharide vaccine manufactured in China.[53] The vaccine conferred 69% efficacy (95% CI = 28%, 87%) over 19 months of follow-up.

Beyond its safety and efficacy in school-age children and adults, an advantage of the Vi vaccine is that it provides a moderate level of protection after just a single dose. On the other hand, there are no robust data to suggest that the efficacy of Vi persists beyond 3 years; efficacy was 55% at 3 years in the South African trial. This concern over the relatively short-lived duration of protection of Vi has been heightened following an epidemiologic investigation of an outbreak of typhoid fever that occurred among Vi-vaccinated French soldiers deployed to Ivory Coast.[125] Prior to the outbreak the standard operating procedure had been to immunize French soldiers with Vi vaccine every 5 years. The outbreak investigation revealed that receipt of Vi more than 3 years earlier was associated with a significantly increased risk of developing typhoid fever during the outbreak.[125] Table 6 summarizes the salient characteristics of Ty21a and Vi vaccines.

9.3.3. New Generation Typhoid Vaccines. New strains of *S.* Typhi that have been genetically engineered to contain precise attenuating mutations have been successfully tested in Phase 1 and 2 clinical trials and shown to be

Table 6. A Comparison of the Characteristics of Live Oral Vaccine Ty21a and Parenteral Vi Polysaccharide Vaccine

	Ty21a	Vi
Type of vaccine	Live	Subunit
Route of administration	Oral	Parenteral
Immunization schedule	3 or 4 doses (given every other day)	1 dose
Cold chain required	Yes	Yes
Well tolerated	Yes	Yes
Efficacy	60–96%	64–72%
Duration of efficacy	7 years	3 years
Evidence of a herd immunity effect	Yes	Yes
Interferes with use of serum Vi antibody as a screening test to detect chronic typhoid carriers	No	Yes

well tolerated and immunogenic after ingestion of just a single oral dose. The live oral vaccine candidates include strains M01ZH09,[165–167] Ty800,[168] CVD 908-*htrA*[169,170] and CVD 909.[171]

Booster doses of purified Vi do not raise antibody titers over those elicited by a single dose of vaccine; i.e., immunologic memory does not appear to occur. To remedy this, Vi polysaccharide has been conjugated to a carrier protein (recombinant exotoxin A of *Pseudomonas aeruginosa*) to increase its immunogenicity by conferring T-cell-dependent properties upon the antigen, including the induction of immunologic memory. In children and adults in endemic areas booster doses of Vi conjugate vaccine clearly increase the titers of antibody over those elicited by a priming dose.[54,55,172] A randomized, controlled field trial of Vi conjugate in children immunized at ages 2–4 years in the Mekong Delta of Vietnam demonstrated 91.5% (77.1–96.6%) vaccine efficacy over 27 months of active surveillance[54] and 82% efficacy during an additional 19 months of follow-up that utilized a passive surveillance system.[55]

10. Unresolved Problems

Areas ripe for research include (1) studies of the role of cytokines and immunopathology in the pathogenesis of typhoid fever; (2) studies of the role and mechanisms of cell-mediated immunity in protection against typhoid fever and the degree to which these are stimulated by live oral vaccine strains[173]; (3) studies of the genetic basis of human susceptibility to clinical typhoid fever[122]; (4) studies to ascertain why infants and toddlers typically manifest mild clinical responses in the presence of bacteremic infection by wild-type *S.* Typhi[56]; (5) the development of practical, inexpensive, rapid assays to make a microbiological confirmation of typhoid fever with a high degree of sensitivity and specificity;[174] and (6) investigations to determine why *S.* Typhi does not readily carry R factor plasmids other than those of incompatibility group H1; (7) further studies of the epidemiology of typhoid and paratyphoid fever in infants, toddlers and pre-schoolchildren that utilize both active and passive surveillance in different sites within the same general population. Finally, should the new generation of recombinant live oral vaccines and parenteral conjugate vaccines realize their potential of being well-tolerated, highly immunogenic and protective public health tools, attention will have to be given to the possibility of worldwide control of typhoid fever. In typhoid-endemic areas, such an undertaking would involve enhanced provision of water supplies and means for human waste disposal, mass vaccination of schoolchildren with the new generation of vaccines, and identification and treatment of epidemiologically relevant carriers.

CHAPTER 44

Yersinia enterocolitica Infections

Ann M. Schmitz and Robert V. Tauxe

1. Introduction

Three bacteria of the genus *Yersinia* are recognized human pathogens. *Yersinia pestis* is the cause of plague, a devastating epidemic disease transmitted from rodent reservoirs to humans by the bite of the flea. *Y. pestis* evolved from *Yersinia pseudotuberculosis*, a cause of epizootic disease in animals and mesenteric lymphadenitis in humans, that can be transmitted through contaminated food.[1] *Yersinia enterocolitica*, recognized as a cause of human illness around the world, also causes intestinal infections and is transmitted from animal reservoirs through contaminated food. The various strains of *Y. enterocolitica* form a heterogenous group of bacteria that includes both well-established pathogens and non-pathogenic environmental strains that are ubiquitous in terrestrial and freshwater ecosystems. Only a few phenotypic variants have been conclusively associated with human or animal disease.[2–4] The principal pathogens for humans are members of a few serogroups (O:3, O:9, O:8, O:5,27). Other strains have been associated with important animal diseases, but the strains that cause human illness are carried asymptomatically in their animal reservoirs and differ from those strains that cause disease in animals.

Illness caused by *Y. enterocolitica* and *Y. pseudotuberculosis* is referred to as yersiniosis. *Y. enterocolitica* is the etiologic agent of a range of clinical entities in humans, although acute enterocolitis is the most frequent manifestation. The bacterium also causes postinfectious sequelae, most notably reactive arthritis. *Yersinia pseudotuberculosis* causes enteritis and pseudoappendicitis, and may also be transmitted through contaminated foods, and is only common in northern Eurasia.[5] The present discussion will focus on *Y. enterocolitica* and its role in a variety of clinical syndromes afflicting humans.

Ann M. Schmitz • University of Wisconsin, Madison, Wisconsin, 53706, USA. **Robert V. Tauxe** • Division of Foodborne, Bacterial and Mycotic Diseases, National Center for Zoonotic, Vectorborne, and Enteric Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia 30333, USA.

2. Historical Background

A description of the organism now known as *Y. enterocolitica* was first published in 1939, by researchers at the New York State public health laboratory, who reported "an unidentified microorganism resembling *Bacterium lignieri* and *Pasteurella pseudotuberculosis* and pathogenic for man", which they subsequently named *Bacterium enterocoliticum*.[6] Similar organisms were reported by various researchers in the following 20 years and given various names, including *Pasteurella X, Y. pseudotuberculosis* type B, *B. enterocolitica*, and Les Germes X.

Following widespread epizootics among chinchillas and hares and after the establishment of a causative relationship with lymphadenitis in man, and in 1964, Fredericksen proposed the species name *Y. enterocolitica* for this taxon.[7] The species *Y. pseudotuberculosis* was distinguished from *Y. enterocolitica* at this time and has since emerged as an important cause of infection in northern Russia and Finland, where it causes illness in hares and deer, as well as human outbreaks that have been associated with consumption of fresh produce.[5,8]

In the 1970s, the organism was recognized worldwide, as improved methods of stool culture facilitated isolation of the organism. While better diagnosis as important, it also appears likely that a global dissemination of pathogenic strains occurred at that time.[9] The recognized incidence of the infection in Belgium and in some other countries began to increase dramatically.[10] Coincident with this heightened

awareness, it became evident that the original biochemical criteria proposed for the species *Y. enterocolitica* encompassed a heterogeneous group of bacteria. Many "*Y. enterocolitica*-like organisms" were described that differed substantially in their biochemical reactions, and several biotyping and serotyping schemes were proposed.[11–13] DNA hybridization techniques finally divided this diverse group of microbes into eight species with distinct biochemical profiles: *Y. enterocolitica, Y. frederiksenii, Y. kristensenii, Y. intermedia, Y. aldovae, Y. rohdei, Y. mollaretii*, and *Y. bercovieri*.[14–16] "*Y. ruckeri*", an economically important pathogen of farmed fish was proposed as a species in 1978.[17,18]

3. Methodology

3.1. Sources of Mortality Data

In developed countries, where most reported yersiniosis cases occur, infection with *Y. enterocolitica* is rarely fatal. Infection most commonly results in enterocolitis. As for many infections, the mortality associated with *Y. enterocolitica* can be difficult to determine, since mortality data are often not collected in pathogen-specific surveillance, and death certificates tend to underreport many pathogen-specific conditions. Pathogen-specific case-fatality has been reported in the active surveillance system, Foodborne Diseases Active Surveillance Network (FoodNet), in the United States,[19] and was included in an overall burden of illness estimate.[20] In a registry-based study linking diagnosis with vital statistics in Denmark, the excess mortality following diagnosis of *Y. enterocolitica* infection could be compared with the mortality in the general population.[21] Syndrome-specific fatality rates for gastroenteritis, mesenteric adenitis, and terminal ileitis are not known; the few fatal cases reported for these clinical syndromes have been attributed to severe complications such as intestinal ulceration and peritonitis. Extraintestinal manifestations of intestinal *Y. enterocolitica* infection are usually self-limited. Clinical disease due to septicemia, most often reported in children or adults compromised by severe anemia, hemochromatosis, cirrhosis, malignancy, malnutrition, or immunosuppressive therapy, is associated with higher rates of mortality. In one nosocomial outbreak, a case–fatality ratio of approximately 50% was reported in 13 patients with disseminated *Y. enterocolitica* infection and a universal mortality in those with underlying hemochromatosis.[22] The complications resulting from disseminated infection, which include suppurative hepatic, renal, and splenic lesions, osteomyelitis, wound infection, or meningitis, and from transfusion-associated yersiniosis, also carry a higher risk of death.

3.2. Sources of Morbidity Data

Many countries maintain surveillance systems to detect infections and estimate burden of illness attributable to specific pathogens, though reporting requirements may vary substantially.[23] In the United States, *Y. enterocolitica* is not nationally reportable and is reportable by law in only 26 states.[24] In 1996 the Foodborne Diseases Active Surveillance Network (FoodNet) began active surveillance for infection by *Y. enterocolitica*, and by other pathogens often transmitted by foods, and now provides annual incidence data.[25] In other countries, such as Sweden, Finland, Ireland and New Zealand, yersiniosis cases are nationally notifiable. Since many clinical laboratories in most countries do not routinely screen diarrheal stool specimens for *Y. enterocolitica*, it is likely to be underdiagnosed and underrecognized by clinicians, and underreported to surveillance. Lack of universal application of laboratory techniques that favor its isolation, as well as incomplete reporting of *Y. enterocolitica* isolates to public health agencies, also limits the completeness of laboratory-based surveillance. Outbreak investigations can provide some additional morbidity data.

3.3. Surveys and Investigations

Surveys of the relative frequency of *Y. enterocolitica* in populations with diarrhea have justified its inclusion as a bacterial enteric pathogen of importance in some parts of the world (Section 5.1). Studies in England and Australia have estimated the pathogen-specific burden of foodborne disease including that caused by *Y. enterocolitica.*[26,27] Serological surveys have been conducted in several European countries (reviewed in[28]). However, direct comparison of the results is difficult, since different subpopulations were studied and since a variety of serological assays and antigens were used.

3.4. Laboratory Diagnosis

3.4.1. Isolation and Identification of the Organism. *Y. enterocolitica* belongs to the family *Enterobacteriaceae*.[29] It is a gram-negative, oxidase-negative, catalase-positive, nitrate-reductase-positive, facultative anaerobic rod that is typically 0.5–0.8 × 1–3 μm in size. Coccobacillary forms may be seen. It does not form a capsule or spores. *Y. enterocolitica* is nonmotile at 35–37°C but motile at 25–27°C, with relatively few, peritrichous flagellae. Some strains of serogroup O:3, however, are nonmotile at both temperatures. In addition, the bacterium is urease-positive, ferments mannitol, and produces acid

but not gas from glucose. *Y. enterocolitica* differs from most members of the family *Enterobacteriaceae* by virtue of its slower growth in general and its ability to grow at refrigerator temperatures.

Bacteriological isolation of the organism is by far the method of choice for diagnosing *Y. enterocolitica* infection. The isolation and identification of the bacterium from normally sterile sites like blood are not difficult using standard bacteriological procedures. Recovery of the organism from stool, on the other hand, is hampered by the lack of distinctive colonial morphology as well as by the organism's slow growth and the resultant overgrowth of normal fecal flora. Several selective media have been developed to enhance the recovery of *Y. enterocolitica* from stool specimens. While routine enteric media can be used in experienced hands, isolation is more easily accomplished on cefsulodin–irgasan–novobiocin (CIN) agar, a highly selective medium used to recover *Y. enterocolitica* from stools. On this agar, *Y. enterocolitica* appears as 0.5- to 1.0-mm diameter colonies with a dark red "bull's eye" and transparent border. CIN agar permits the growth of all pathogenic serogroups.[30] Two selective media, *Salmonella–Shigella*–deoxycholate–calcium (SSDC) agar and irgasan–ticarcillin–potassium chlorate (ITC) enrichment broth, have been specially designed for isolation of O:3, the most common serogroup.

The use of a cold enrichment step at 4°C can facilitate recovery of *Y. enterocolitica* when the bacterial density is low, such as in the convalescent phase of an infection. However, this procedure may require incubation for weeks and is likely to lead to isolation of non-pathogenic strains, making it of little clinical use.[31] Isolates of *Y. enterocolitica* identified in this fashion must be further characterized before diagnostic conclusions are drawn.

Y. enterocolitica is quite heterogeneous with respect to phenotypic, genotypic, and ecological properties. The phenotypic heterogeneity has enabled the development of several schemes for subdivision of the bacterium. Serogrouping according to O antigens and differentiation of biotypes on the basis of biochemical properties have been the most useful typing methods. *Y. enterocolitica* has been divided into approximately 60 serogroups using O antigens.[13] Several O antigen groups may be further subdivided by H antigens. However, the use of H-antigen typing has been hampered by its variable expression and limited availability. The biotyping scheme proposed by Wauters has been widely used; a revision was published in 1987.[32] In addition to serogrouping and biotyping, a number of phenotypic and genotypic methods have been used to subdivide *Y. enterocolitica*. The discriminatory power of the genotypic methods may be higher for serogroup O:8 than for O:3, O:9, and O:5,27.[33] Molecular subtyping as part of public health surveillance to improve the detection of diffuse outbreaks has not yet been implemented in a routine way for *Y. enterocolitica*, as it has been for *Escherichia coli* O157 and *Salmonella* in the US PulseNet system, though it is likely to be in the future.

In clinical and research laboratories, subtyping is important because *Y. enterocolitica* strains vary in their ability to cause disease, and many strains have no established pathogenic significance. Surveys of the environment or of foods conducted without subtyping may identify many *Y. enterocolitica* strains that are of no public health significance. Fortunately, the great majority of the strains that cause illness in humans or animals belong to only a few serogroups and biovars.[2] Somewhat simplified, *Y. enterocolitica* may be divided into three groups according to clinical significance: human pathogens, animal pathogens, and environmental strains, each with different serogroups. The most important human pathogens are O:3 biovar 4; O:5,27 biovar 2; O:8 biovar 1B; and O:9 biovar 2, though other serogroups may occasionally cause infection.

The strains that are pathogenic for animals include O:1 biovar 3, responsible for widespread outbreaks in chinchillas; and O:2 biovar 5, associated with disease in hares, sheep, and goats.[34] The environmental strains include a spectrum of phenotypic variants with a variety of other serogroups; most belong to biovar 1A. These bacteria usually lack human clinical significance. Such environmental strains have occasionally been involved in human infection, mainly in immunocompromised patients and patients with underlying conditions.

Y. enterocolitica may be differentiated from other species of the genus by means of several distinct biochemical reactions, and other phenotypic differences. The "*Y. enterocolitica*-like organisms" include *Y. frederiksenii, Y. kristensenii, Y. intermedia, Y. aldovae, Y. rohdei, Y. mollaretii*, and *Y. bercovieri*.[29] Such species are frequently encountered in terrestrial and freshwater ecosystems. Like the environmental *Y. enterocolitica* strains, these species have not been associated with human or animal disease, with rare and atypical exceptions. *Y. ruckeri*, an important cause of illness in farmed trout, is not linked to human illness.[18]

3.4.2. Serological Diagnostic Methods. Serodiagnosis has been developed for research purposes, but is not often used for routine diagnosis.[35] Infection with *Y. enterocolitica* elicits an immunologic response that can be measured by a variety of techniques, including tube agglutination, indirect hemagglutination, enzyme-linked immunosorbent assay, and indirect immunoflurorescent-antibody assay. [36–38]

Agglutinating antibodies appear soon after the onset of illness and persist for 2–6 months. Patients with systemic infection produce a higher antibody titer than do persons with disease restricted to the gastrointestinal tract.[35]

Cross-reactions complicate the serological diagnosis of *Y. enterocolitica* infection. Some of these are with other bacteria. For example, *Y. enterocolitica* serogroup O:9 shares cross-reacting antigens with *Brucella.*[29] Antibodies to thyroid hormone receptors, which are elevated in autoimmune hyperthyroiditis (Graves disease), have been described that also have a cross-reacting affinity to *Y. enterocolitica* antigens, though the bacteria play no role in thyroiditis.[39,40] The detection of antibodies by immunoblots to certain plasmid-encoded proteins, the *Yersinia* outer membrane proteins (Yops), has been suggested as a highly specific method to demonstrate previous *Y. enterocolitica* infection.[41,42] Demonstration of specific circulating IgA to the Yops is indicative of recent or persistent infection and is strongly correlated with the presence of virulent *Y. enterocolitica* in the intestinal lymphatic tissue of patients with reactive arthritis.[43]

4. Biological Characteristics of the Organism

Y. enterocolitica is psychrotrophic, which means it can multiply at temperatures approaching 0°C, and grow in properly refrigerated foods.[44] This provides *Y. enterocolitica* with a competitive advantage over many other bacteria for propagation in environmental reservoirs. The growth of *Y. enterocolitica* on cooked meats and in milk at low temperatures is well documented. However, the presence of other psychrotrophic organisms in food may inhibit growth of *Y. enterocolitica*.[45,46] *Y. enterocolitica* can survive in frozen foods for long periods.[44] Most virulent strains behave differently depending on temperature. At room temperature (25–27°C), they express flagella and so are motile and express few virulence factors; while at 37°C, most strains are nonmotile, but express an array of virulence factors.[2,47] This temperature dependence of biologic characteristics may be important for survival of the organism outside of the host and for pathogenesis in the host.

Y. enterocolitica is relatively iron dependent. Unlike most other aerobic bacteria, most strains of *Y. enterocolitica* do not produce iron-binding compounds, or siderophores, and instead depend on siderophores produced by other bacteria to capture the iron needed for growth. They are also able to use hemin as a source of iron.[48] Particularly severe infections can occur in patients who already have conditions of iron overload, especially during treatment with iron chelators that mobilize body iron, and may make it more easily available.[49] *Y. enterocolitica* are also relatively calcium dependent, and most virulent strains require calcium-supplemented media to grow at 37°C. It is thus not a great surprise that outbreaks of yersiniosis are often traced to vehicles that are rich in calcium and iron and that are held refrigerated and consumed cold.

The virulence of human pathogenic strains of *Y. enterocolitica* has been intensively studied and depends on a variety of molecules and mechanisms. Several of these are mediated by the virulence plasmid of approximately 70 MD, known as pYV.[50] The presence of the plasmid is tightly correlated with calcium-dependent growth at 37°C. Similar plasmids are also present in *Y. pseudotuberculosis* and *Y. pestis.* Although many virulence determinants are encoded on the chromosome, the presence of the plasmid is an important marker for virulence. The same plasmid also carries a gene for arsenic resistance, and it has been suggested that the widespread use of arsenicals in the past to treat swine dysentery and other infections of pigs may have selected for the presence of the plasmid.[51]

Production of urease occurs at 25–27°C. The action of this enzyme releases ammonia from urea that is present in the mucous layer of the stomach, buffering local gastric acidity, and providing relative acid resistance.[52] Adherence and invasion of the mucosal cells occurs via invasin and other surface proteins that are chromosomally encoded.[53] The organism produces several additional proteins that enable it to escape host defense mechanisms, including phagocytosis and the bactericidal action of serum. Two such proteins, Ail (attachment invasion locus) and YadA (*Yersinia* adhesin A), are adhesins that also confer resistance to complement-mediated opsonization. The most complex of these virulence proteins are the plasmid-mediated*Yersinia* outer membrane proteins (Yops).[54] The Yops are not simple outer membrane proteins, but an extraordinary array of effectors that are produced in the bacteria, then secreted and inserted into host cells via a type III secretion system.[55] The injector apparatus is assembled and armed on the surface of the bacteria at 37°C, and the Yops are injected on contact with the target cell. The injected Yops have an array of effects on the cells of the mammalian host. They rapidly paralyze phagocytes, block secretion of recruitment molecules such as TNF-alpha and IL-8, and appear to inhibit activation of macrophages.[55,56] The cumulative effect is that inflammation is suppressed and phagocytosis evaded. In addition, a few strains have genes for an iron-binding siderophore known as yersiniabactin, which can efficiently bind iron in iron-deprived sites, permitting continued rapid growth.[57] Similar virulence mechanisms have been described in *Yersinia pseudotuberculosis*.

While virulence factors for attachment and invasion explain invasion and systemic infection, they do not by themselves account for diarrheal illness. A better candidate for that characteristic is a specific *Yersinia* heat-stable

enterotoxin, Yst, which is similar to the heat-stable enterotoxin of enterotoxigenic *E. coli.* This toxin is produced under a specific combination of temperature, pH, and osmolality resembling that of the mammalian ileum.[58,59] It is found almost exclusively and universally in pathogenic strains of *Y. enterocolitica.*[60]

Not all strains possess all these mechanisms. The so-called high pathogenicity island that codes for yersiniabactin and perhaps other virulence factors is present only in *Y. pseudotuberculosis* and biotype 1B of *Y. enterocolitica.*[57] Although in general, *Y. enterocolitica* biotype 1A has been regarded as avirulent, some strains have been described that appear to be enteropathogenic, though they lack pYV and other known virulence determinants.[61,62] It is likely that more virulence determinants remain to be identified.

A number of assays have been used to differentiate pathogenic and non-pathogenic variants. Most test for the presence of the pYV plasmid, using such markers as autoagglutination at 37°C, calcium-dependent growth restriction at 37°C, resistance to the bactericidal activity of normal human serum, binding of Congo red dye, ability to invade various cell cultures, or by direct DNA sequence probing.[44,6364] Autoagglutination and calcium-dependent growth have been the most widely used in vitro tests, though no single property appears to be an absolutely reliable indicator of the pathogenic potential. The striking correlation between potential pathogenicity and lack of pyrazinamidase activity, independent of the occurrence of the virulence plasmid, makes this a useful test, which is included in the revised Wauters biotyping scheme.[32] One practical approach combines pyrazinamidase, calcium-dependence, Congo red dye uptake, and phenotypic assays to screen for pathogenic strains.[65]

5. Descriptive Epidemiology

5.1. Prevalence and Incidence

Y. enterocolitica infections were recognized in the 1970s when global awareness increased and a widespread dissemination may have occurred with real subsequent increases in incidence.[9,66] In Belgium, Finland, Germany, New Zealand and Sweden, *Y. enterocolitica* surpassed *Shigella* to rival *Salmonella* as a cause of acute bacterial gastroenteritis. Recently reported incidence varies substantially from country to country, from <0.1 per 100,000 in France and Portugal to 13.6 per 100,000 in Lithuania (Table 1).

Several studies have estimated the overall burden of illness due to yersiniosis, adjusting for likely underreporting. In an analysis based on FoodNet data, the reported incidence of positive cultures in the time span 1996–1999 was 0.8/100,000, but after adjusting for the proportion of laboratories that do not routinely seek the organisms that incidence was estimated to be 5/100,000 among those ill enough to seek care and be cultured.[67] Broader approaches that estimate the numbers of all illnesses, rather than just those being cultured, arrive at substantially higher estimates. It was estimated that in 1997 in the United States, *Y. enterocolitica* caused 96,000 illnesses, 1,228 hospitalizations, and 3 deaths, of which 90% was foodborne in origin, yielding an estimated incidence of 36 per 100,000.[20] Using a similar approach, Australian investigators estimated that in 2000, yersiniosis accounted for 2,200 infections and 34 hospitalizations, of which 75% was foodborne in origin, an estimated incidence of 115 per 100,000.[27] Using data derived from reported foodborne outbreaks, English investigators estimated that the annual burden of yersiniosis in England and Wales, 1996–2000, was 129,000 cases of illness, 619 hospitalizations, and 3 deaths, an estimated annual incidence of 250 per 100,000.[67a]

Table 1. Annual Incidence of *Yersinia* Infections in Selected Countries with Surveillance

Country	Year	Incidence rate per 100,000 population	Reference
Australia	2004	1.3	[79]
Austria	2004	1.4	[80]
Belgium (Flemish Community)	2004	4.8	[80]

United Kingdom	2004	0.1	[80]
United States	2005	0.36	[25]

*Only hospitalized cases are reported.

The incidence of illness in a country may change importantly over time. In Belgium, surveillance was started in 1967[68] and documented an important increase in incidence in the 1970s.[10] Some of the early part of the increase may have been due to improved diagnosis and reporting, but much of it appeared to be a real increase. The number of cases reported quadrupled from 305 cases in 1975 to 1,469 in 1986, an incidence of approximately 14.7 per 100,000, and then declined to 7.1 per 100,000 by 1996.[68] As in other European countries, serotype O:3 was the dominant serotype, representing 79% of strains from 1967 to 1996, though this proportion dropped over time. Factors thought to play a role in this increase included changes in the breeding practices of swine, in slaughter methods that include trimmed tonsil meat in ground pork, and traditional food habits in Belgium which include regular consumption of undercooked or raw ground pork.[69] Changes in slaughter practice to reduce contamination of ground pork with tonsil tissues, and an education campaign about the hazards of raw pork may have contributed to the decline. In the United States, the incidence of yersiniosis tracked in FoodNet has decreased by 49% from 1996 to 2005, for reasons that remain to be clarified.[25]

In New Zealand, infections due to *Y. enterocolitica* has increased since the late 1980s.[70] The frequency of isolation of *Y. enterocolitica* from specimens in the Auckland area rose from 0.2% in 1987 to 0.5% in 1989. The most common serogroups seen at that time were O:3 (92%) followed by serogroup O:5/27 (4%) of isolates. In a study conducted on stool samples collected in the Auckland area 1988–1993, *Y. enterocolitica* was identified as the third most common enteric pathogen isolated after *Campylobacter* and *Salmonella*.[71] Serogroup O:3 was most frequently recovered and there was no seasonal pattern. Since the 1990s, the incidence of yersiniosis in New Zealand has been one of the highest in the world and was 10.9 per 100,000 in 2005.[72]

The reported proportion of acute diarrheal illness due to *Y. enterocolitica* has varied depending on geographic location, time, population, and study. In one study conducted at the peak of the Belgian epidemic, the percentage of routine stool cultures yielding *Y. enterocolitica* of serogroups O:3 and O:9 was as high as 2.5%.[73] In an early study in Canada, *Y. enterocolitica* was isolated from 2.8% of the stools submitted at pediatric hospitals.[74] The frequency of yersiniosis was greater than shigellosis (1.1%) and less than salmonellosis (4.4%) and was most commonly associated with serogroup O:3. In a study of pediatric gastroenteritis in the United States, conducted at the highest risk time of year, and in a city and population known to be affected, 76 (1%) of 7,290 stool cultures yielded *Y. enterocolitica.*[75] Studies with lower yield have also been published. In a study in the Netherlands, conducted in 1996–1999 to determine the overall burden of enteric infections, 5 (0.5%) of 857 stools from diarrheic patients yielded *Y. enterocolitica*, but none of the 5 were pathogenic serotypes, and the yield was no different from the cultures of healthy controls.[76] Similarly, an exhaustive study of pediatric gastroenteritis recently conducted in Seattle in the United States found only 2 (0.1%) of 1,626 stools yielded *Y. enterocolitica.*[77]

The yield of diagnostic culture may be higher in specific syndromes. Several studies of patients with the appendicitis-like syndrome have found *Y. enterocolitica* in up to 9% of patients. In Belgium, the isolation rate of *Y. enterocolitica* from appendices removed for clinical appendicitis was 3.8%.[73] In a report of 581 persons who underwent appendectomy for presumed appendicitis over a 1-year period in Sweden, 22 cases (3.8%) had bacteriological evidence of *Y. enterocolitica* infection.[78] Of those found to have regional terminal ileitis at surgery, 80% were infected with *Y. enterocolitica*, as were 13% of those with mesenteric adenitis, and 0.5% of those with acute appendicitis. Although sometimes present in asymptomatic individuals, surveys have found carriage rates of less than 1% in asymptomatic controls.[74]

The case–fatality rate reported for diagnosed cases of *Y. enterocolitica* infection in FoodNet was 0.77% for the period 2000–2004.[19] The crude 30 day excess mortality reported from the Danish registry study was 0.14%.[21] The same investigators reported that the death rate was significantly elevated out to 180 days after diagnosis even after adjusting for underlying illness.

5.2. Epidemic Behavior and Contagiousness

Outbreaks of yersiniosis traced to specific sources are unusual, but illuminating (Table 2). It is curious that in recent years, while both clinical awareness and public health surveillance for yersiniosis have been good and improving in a number of countries, very few outbreaks are reported. For example, in 2004, none were reported in Australia,[79] and only two, affecting a total of eight persons were reported in New Zealand.[72] In 2004 in Europe, a total of 51 outbreaks of yersiniosis were reported, affecting a total of 182 persons. However, for only two outbreaks was a source was reported, one of which was an outbreak of *Yersinia pseudotuberculosis* infections in Finland affecting 58 persons.[80] The remaining outbreaks, affecting a mean of 2.5 persons each, were reported from Austria, Czech Republic, Denmark, Germany and Portugal, and a source (raw ground beef) was identified for only one. While few well-characterized outbreaks of enteritis due to *Y. enterocolitica* have been reported in Europe, several major outbreaks have been described in the

Table 2. Outbreaks of *Y. Enterocolitica* Infections with Identified Route and Vehicle of Transmission

Author	Year published	Location	No. ill	Mode of transmission/vehicle	Serogroup	Reference
Gutman et al.	1973	North Carolina (family)	16	Contact with sick puppies?	O:8	[81]

Jones	2003	Tennessee	12	Contact with preparation of chitterlings	O:3	[114]
Sakai	2005	Japan (nursery school)		Cold mixed salad	O:8	[93]

United States. The first of these was puzzling. In 1972, 16 of 21 individuals from four linked families were affected in rural North Carolina.[81] The outbreak resulted in two exploratory laparotomies and two of the afflicted individuals died, one following surgery. A serogroup O:8 *Y. enterocolitica* was isolated from the spleen of a fatal human case, and eight others had serologic evidence of recent infection. Although the source was not confirmed, five of nine newborn puppies associated with one family had died with diarrheal illness during the week before the first human illness.

Food is the most common vehicle of transmission in outbreaks of *Y. enterocolitica* infection. Several outbreaks involved commercial milk, which likely became contaminated after pasteurization. The first of these occurred in 1976, in upstate New York.[82] Illness occurred in 222 school children and employees, 38 of whom had documented *Y. enterocolitica* serogroup O:8 infection; 36 individuals were hospitalized and 16 appendectomies were performed. Illness was associated with the consumption of chocolate milk purchased in the school cafeteria. *Y. enterocolitica* was subsequently isolated from a carton of chocolate milk. As no defects in pasteurization were identified, it was presumed that contamination occurred afterwards, possibly during introduction of chocolate flavor or vitamins.

In 1982, a multistate outbreak caused by serogroups O:13 and O:18 caused illness in at least 172 persons; 17 individuals underwent appendectomy and 24 cases of extraintestinal disease were documented.[83] Illness was associated with drinking pasteurized milk from a Memphis, Tennessee plant. Samples from the incriminated lots of milk were not available for culture. Again, no flaws in pasteurization were identified. A survey revealed that 8.3% of those who drank the milk became ill; the attack rate was 22.2% in children 0–4 years old and 38.5% in children 5–9 years old. In a third outbreak, 53% of persons at a camp experienced illness caused by *Y. enterocolitica* serogroup O:8, and the investigation showed that illness was associated with consumption of reconstituted powdered milk and/or chow mein.[84] The

organism appeared to have been introduced by an ill food handler during preparation.

In 1985, a cluster of infections with *Y. enterocolitica* serogroups O:10 and O:6,30, biovar 1 was identified in a pediatric ward in Great Britain, and few of the children had diarrhea or abdominal pain; culture of the feces of 34 yielded one or the other serogroups.[85] The same strains were isolated from pasteurized milk from a local dairy, delivered to the hospital. Intensive investigation of the dairy indicated that although there was no defect in the pasteurization itself, the organism could be recovered from freshly pasteurized milk from the bottle filling line, before it entered the bottles, though not from milk from a carton filling line; a nidus of contamination in the bottle filling apparatus was suspected.[86] In 1995, an outbreak of serogroup O:8 caused illness in 10 patients from Vermont and New Hampshire in 1995.[87] Three of these patients were hospitalized and one underwent appendectomy. Consumption of pasteurized milk from a local dairy was significantly associated with disease. *Y. enterocolitica* was isolated from one raw milk sample and from a fecal sample from a dairy pig. As no defects in pasteurization or filling apparatus were identified, it was suspected that the organism could have been transferred in some fashion from the pigs to the clean bottles waiting to be filled.

Pork is the most important source of sporadic cases of yersiniosis and has also been identified as the vehicle of community outbreaks. In the United States, an outbreak of bacteremia and gastroenteritis was recognized in African-American infants in the winter of 1988–1989.[88] The infants were all formula fed, but the formula was of a variety of brands and types, and so was unlikely to be the source of contamination. The ill infants had been cared for by persons who were simultaneously preparing chitterlings, a dish of boiled pork tripe. In the course of preparation, *Yersinia* appears to have been transferred from the raw tripe to the infants on the unwashed hands of the caregiver. *Y. enterocolitica* serogroup O:3 biovar 4 was isolated from 8 of 15 samples of raw pork tripe, as well as from the patients. This outbreak heralded the emergence of this subtype in the United States.

Water may also be a source of contamination of foods. An outbreak of 44 *Y. enterocolitica* infections occurred in Washington between December 1981 and February 1982.[89] Disease was associated with the ingestion of contaminated tofu (soybean curd), and *Y. enterocolitica* serogroup O:8 was isolated from afflicted individuals. Culture of the tofu, as well as of the untreated spring water used in the tofu manufacturing plant, yielded the same serogroup, O:8. A second outbreak involved 16 of 33 (48%) members of a Brownie troop who were infected following the ingestion of bean sprouts that had been grown in refrigerated water from a well that was shown to be contaminated with *Y. enterocolitica*; 15 of the children manifested gastrointestinal symptoms an average of 6 days following exposure and three underwent appendectomy.[90]

In Japan, epidemic *Y. enterocolitica* enteritis has been described in communities and schools, but without epidemiologic or microbiologic implication of specific sources.[91,92] One such outbreak occurred in 1972 in a Japanese junior high school where acute abdominal pain and fever were present in 198 of 1,086 pupils.[92] *Y. enterocolitica* serogroup O:3 was isolated from the fecal specimens of the majority of ill children; however, a common source of contaminated food or water was not identified. In 2003, an outbreak affected 42 children at a nursery school in Nara, 16 of which were confirmed by culture as serogroup O:8, biovar 1B; the same strain was isolated from a cold salad served to them the week before.[93]

It is noteworthy that sustained person-to-person transmission does not occur with yersiniosis. Rare nosocomial outbreaks (described in Section 5.9) suggest that person-to-person transmission may have occurred, and thus that routine enteric precautions are warranted. The powdered milk outbreak reported above suggests that an infected foodhandler may be a source, again suggesting that routine foodhandler precautions are warranted.

5.3. Geographic Distribution

Y. enterocolitica has been isolated from humans in many countries of the world but is found most frequently in cooler climates. Yersiniosis is most commonly reported in northern European countries, or in New Zealand in the Southern Hemisphere, and is rarely reported in tropical countries.[66] This distribution may reflect differences in frequency of infection in food animal reservoirs and in culinary practices, as well as more intensive surveillance and appropriate culturing techniques in these areas.[94] The infrequent occurrence of *Y. enterocolitica* in some areas of the world may be due in part to culinary habits, such as avoidance of pork in Muslim countries.

Differences in the distribution of the different serotypes of *Y. enterocolitica* isolated from humans appear to be disappearing. Serogroup O:3 biovar 4 is the most widespread in Europe, Japan, Canada, Africa, North America and Latin America. Serogroup O:9 biovar 2 is the second most common in Europe, but its distribution is uneven; while it accounts for a high percentage of the strains isolated in France, Belgium, and the Netherlands, only a few strains have been isolated in Scandinavia.[95] The relative proportion Serotype O:8 was first reported in Europe in the mid-1980s, when a study in the Netherlands showed 25% of all infections were caused by serotype O:8.[37] Until the 1990s the most

frequently reported serogroups in the United States were O:8 followed by O:5,27. In more recent years, serogroup O:3 has been on the increase in the United States in both endemic and epidemic infections.[96] This suggests that the epidemiology of yersiniosis in the United States has evolved into a pattern similar to the picture in Europe, where serogroup O:3 predominates.

5.4. Temporal Distribution

A clustering of cases during the cold fall and winter months has been reported in some European countries, such as Belgium.[73] A similar seasonality has been reported for the frequency with which *Y. enterocolitica* is isolated from swine and from pork, so the seasonality of infections in the swine reservoir may drive the seasonality of infection in humans.[97–99] The association of *Y. enterocolitica* with cooler seasons and temperate climates may be linked to the organism's ability to multiply at low temperatures (see Section 4). In the United States, a study from the early 1990s documented a sharp increase in the number of cases in winter months (December, January, February).[75] More recently, this sharp winter peak in cases has recurred annually (See Figure 1).[67] In Australia, one study found that the peak isolation period for *Y. enterocolitica* from children was in the warm months of December – March.[100]

5.5. Age

Although *Y. enterocolitica* causes a number of clinical syndromes that vary with the age, sex, and health of the host, children appear to be preferentially affected. Of 359 infected patients reported by Mollaret, 47% were between 1 and 5 years of age.[101] Vandepitte and Wauters reported 1,711 cases of *Y. enterocolitica* infection occurring in persons less than 1 month to 85 years old; approximately 20% of all cases occurred within the first year of life.[10] Nearly 80% of patients were less than 10 years old. In the United States, the incidence of infection is greatest in the age group less than 1 year old, among whom the incidence is 25/100,000, compared to 2.7 per 100,000 for children aged 1–4, 0.4 among persons aged 5–59 years, and 0.5 per 100,000 among persons aged 60 or more.[67] In a review of 142 patients with stool cultures yielding *Y. enterocolitica* at a Children's Hospital in the United States, the median age of patients was 5 months with an age range of 18 days to 12 years. Of these children, 85% were 12 months of age or younger.[102] The illness most commonly associated with *Y. enterocolitica* in children less than 5 years old is a febrile diarrheal illness, indistinguishable from that caused by other enteric pathogens (see Section 8.1). Infants less than 3 months old with *Yersinia* enteritis are at greater risk for bacteremia.[102,103] Children over 5 years old are more likely to develop symptoms that mimic those of acute appendicitis. A dramatic difference in age-specific incidence was noted when patients with enteritis were compared with those with the appendicitis-like syndrome.[104] While 80% of all patients with enteritis were less than 5 years old, those with a pseudoappendicitis syndrome were most frequently older children and adults. Most extraintestinal manifestations of *Y. enterocolitica* infection, including the postinfectious sequelae, are more frequently found in adults than in children. In hospital outbreaks, it has been noted that the old and the very young were more often infected and may be predisposed by age and physical condition, including immune status.[105]

5.6. Sex

In general, rates do not differ by sex. In most studies, males have slightly outnumbered females in all age groups of

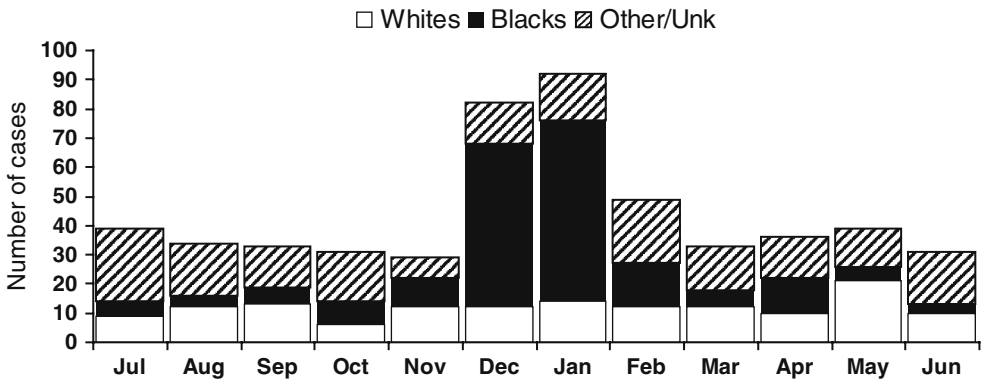

Figure 1. Reported cases of yersiniosis, by month and ethnicity, FoodNet catchment area, United States, 1996–1999, adapted from [67].

patients with *Y. enterocolitica* diarrhea. For example, in one Belgian study, the sex distribution of patients with *Y. enterocolitica* showed more males (54.7%) relative to females.[73] Surveillance data in New Zealand for 2005 showed higher incidence in males (11.8 per 100,000) than females (9.4 per 100.000).[72] In FoodNet, the rates for 2004 were 0.47 per 100,000 in males and 0.39 in females, though these rations are reversed in other years.[19] The sexes tend to be equally affected in outbreaks of mesenteric adenitis. Erythema nodosum is seen more commonly in females.[106]

5.7. Occupation

The organism has been found frequently in samples from swine in slaughterhouses, where it may readily be transferred to employees at all stages during slaughtering and processing (see Section 6). Seroepidemiological studies have indicated that occupational exposure to pigs is a risk factor.[107,108]

5.8. Race and Ethnicity

Race and ethnicity are important because they may reflect differences in specific exposures. In the United States, the incidence of yersiniosis is low among whites (0.5 per million), whereas among African-Americans the incidence of infection is higher (3.4 per 100,000).[67] The highest rates of all were seen African-American infants among whom the incidence of culture-confirmed infections was 143 per 100,000. The winter peak was largely driven by infections in the African-American population, probably because of the seasonal exposure to chitterlings (Figure 1). Rates of infection have been shown to be lower in Muslim populations, which avoid pork.[69] In New Zealand, the highest rates of infection (20.8 per 100, 000) were reported among those of ethnic backgrounds other than European, Maori, and other Pacific Peoples, followed by those of European ethnicity (9.1 per 100,000). The lowest rates were reported among Maori (4.9 per 100,000) and Pacific Peoples.[72]

5.9. Occurrence in Different Settings

Y. enterocolitica among hospital populations typically occurs as sporadic illness and very rarely as outbreaks (Table 2). Some underlying health conditions, such as iron overload and HIV infection, can predispose persons to yersiniosis. Excess iron favors growth and virulence of this iron-dependent organism. The first nosocomial outbreak of *Y. enterocolitica* was reported from Finland in 1973 and involved six hospital employees who became ill approximately 10 days after a schoolgirl with *Y. enterocolitica* enteritis was admitted to their hospital. Spread of the infection, in this and other hospital outbreaks, appeared to be from the index patient to the staff and subsequently from person to person.[109] Another nosocomial outbreak occurred in Canada in 1980, in which nine patients in total were identified, some only by enrichment culture, with possible transmission from the index patient through fomites.[105] In a study of sporadic *Yersinia* infections in hospitalized patients conducted 1987–1990, it was reported that 5 of 18 had developed diarrhea after being hospitalized for unrelated conditions, and thus were likely to represent nosocomial infections.[110]

Outbreaks have been reported among children attending institutions for collective care in eastern Europe, in which a foodborne source was suspected, though not proven.[111] A number of outbreaks have occurred in schools in Japan, without an identified source.[91]

5.10. Socioeconomic Factors

There is little published information suggesting that socioeconomic factors affect the occurrence of *Y. enterocolitica* infection.

6. Mechanisms and Routes of Transmission

Y. enterocolitica can be transmitted through food, water, and occasionally by contact with animals. Rare transfusion-associated cases have also been reported. Transmission by person-to-person contact is also rare. Foodborne transmission is the most common route for sporadic infections and is predominantly associated with consumption of pork. An epidemiological case–control study of sporadic yersiniosis in Belgium documented the importance of consumption of undercooked or raw ground pork, often in the form of raw pork meatballs consumed informally in the kitchen during food preparation.[69] In Norway, an epidemiological case–control study showed that cases of yersiniosis were strongly associated with eating undercooked pork and sausage products and that they generally preferred their meat to be either raw or rare, though very few reported actually eating raw pork.[112] In New Zealand, an epidemiological case–control study of sporadic cases also showed a strong association with eating pork, though the extent of cooking was not established.[113] In 1988–1989, as noted above, an outbreak of infection due to serogroup O:3 among African-American infants in the United States showed that

preparation of raw pork intestines as a holiday food known as chitterlings by the infant's caregiver was significantly associated with illness.[88] Since that outbreak, similar winter clusters have been investigated, with similar findings. Surveys in four cities in the winter of 1989–1990 identified clusters of infections around the holidays of Thanksgiving, Christmas, New Years, and Martin Luther King Day.[96] In 2001, a cluster of 12 cases of *Yersinia* gastroenteritis in black infants was investigated in Tennessee, all of which were exposed to preparation of chitterlings, compared to only 35% of ethnicity and age-matched controls.[114] Exposure was often indirect, and was not necessarily through the caregiver, leading the authors to recommend that chitterlings be routinely irradiated. A cluster of nine infants in Chicago with *Y. enterocolitica* gastroenteritis were investigated in the winter of 2002–2003; of these eight had exposure to chitterlings, and serotype O:3 was isolated both from children and from chitterlings.[115] Raw pork contamination is particularly likely for offal, and ground pork, and strains isolated from pork are difficult to distinguish from those isolated from humans.[3,33]

Untreated drinking water can be another source of sporadic yersiniosis. Consumption of untreated surface water was identified as a risk factor for infection with serogroup O:3 in the case–control study in Norway.[112] Similarly in New Zealand, being connected to the town water supply was significantly protective, suggesting that drinking untreated water was associated with infection.[113]

Y. enterocolitica has been isolated from many domesticated animals and wildlife. Frequently these strains are different from those that have been shown to infect humans. Swine are frequently healthy reservoirs for strains pathogenic to humans, such as serotype O:3 and serotype O:9. In a survey of swineherds conducted in 2000 in the United States, 3.8% of 2,793 fecal samples yielded *Y. enterocolitica* that were ail-positive, and of these 79% were serotype O:3 and had the pYV plasmid.[116] The same survey found that at least one pig was positive on 47% of premises sampled. A survey of pigs at slaughter in Norway found 12% positive for *Y. enterocolitica* serotype O:3, biotype 4, and a similar survey in Sweden found 8% positive.[117] In Sweden, strains of *Y. enterocolitica* isolated from pork had the same pulsed-field gel electrophoresis patterns as those isolated from patients.[118] Dogs, cats, and rodents may occasionally be fecal carriers of serogroups O:3 and O:9, and apparent transmission from dogs and cats to humans has been reported.[119] Rodents were identified as a possible source of infection with serogroup O:8 in Japan.[120]

Some of the most serious, though rare, cases of yersiniosis have resulted from blood transfusions.[121] Ten such cases were reported in the United States between 1991 and 1996 and cases have been reported in other countries as well.[121] A prospective study conducted in the United States between 1998 and 2000 showed that the incidence of transfusion-associated cases of *Yersinia* sepsis was 1 per 23.7 million red cell transfusions.[122] Such cases typically follow transfusion of packed red cells that had been held refrigerated for several weeks after donation. It is presumed that the donors had undetected bacteremia and that the bacteria had the opportunity to multiply during the holding time. Following experimental inoculation into packed red cells at 4°C, *Y. enterocolitica* enter log phase growth in the third week and produce high levels of enterotoxin by 28 days.[123] Just such an asymptomatic bacteremia was detected in a blood donor via routine screening, though the recipient, who was receiving broad spectrum antibiotics at the time of transfusion, had no ill effects.[124]

7. Pathogenesis and Immunity

Human infection with *Y. enterocolitica* is usually acquired by the oral route. The dose required to cause disease in humans is unknown, though one volunteer became ill after consuming 3.5×10^9 organisms.[104] The incubation period typically averages 4–6 days in the outbreak setting. Following ingestion, enteric infection leads to proliferation of *Y. enterocolitica* in the lumen of the bowel and in the lymphoid tissue of the intestine.[44] Secretion of enterotoxin while in the lumen presumably is related to the onset of diarrhea. In the terminal ileum, the bacteria enter the layer of mucous on the gut surface and adhere to the luminal membrane of the enterocytes of the gut wall. Once they penetrate and traverse the enterocyte, they show tropism for the gut-associated lymphoid tissue and multiply in the Peyer's patches and mesenteric lymph follicles, causing a massive inflammatory response. In a self-limited infection, the bacteria are then gradually eliminated. In some persons at higher risk, particularly those with iron-overload syndromes, infection can disseminate from the gastrointestinal tract through the portal vein to produce distant infections throughout the body.

When the localized abdominal pain and fever suggest appendicitis, the patient may wind up on the operating table. The findings at surgery in patients with terminal ileitis are grossly visible, and nearly pathognomonic of yersiniosis. They include extensive mesenteric adenopathy with matted lymph nodes. When tissue is removed and examined microscopically, the pathologist notes cellular infiltrates include lymphoid hyperplasia, epithelioid granulomas, and necrotic suppurative lesions in which the gram-negative organisms are easily demonstrated.

Human infection with pathogenic strains of *Y. enterocolitica* stimulates development of specific antibodies. Although there is considerable evidence that both natural and experimental infection can confer some degree of immunity, the degree to which it is serogroup-specific, and the precise extent and duration of such immunity remain to be determined. In mice, infection with plasmid-containing strains of *Y. enterocolitica* protects against subsequent challenge with *Yersinia pestis*.[125,126]

The postinfectious syndromes appear to be related to the immunologic response to the intestinal infection. The pathogenesis of reactive arthritis caused by *Yersinia* infection is likely to be related to an immune response to *Yersinia* antigens that cross-react with host antigens in susceptible persons. However, the nature of the putative inciting *Yersinia* antigen has not been determined. Host tissue type is the predominant co-factor; HLA-B27 is typically present.[127–129]

T-cells derived from the joint fluid of patients with reactive arthritis have been reported to selectively kill HLA-B27-bearing cells that are also infected with *Y. enterocolitica*.[128] Patients with *Y. enterocolitica*-induced reactive arthritis show a chronically elevated IgA level to a series of virulence-associated, plasmid-encoded proteins (Yops) that are produced by the bacterium.[41,42] Erythema nodosum, the other common post-yersiniosis sequel, does not appear to be associated with HLA-B27.[129]

8. Patterns of Host Response

8.1. Clinical Features

Y. enterocolitica infections in humans can range from asymptomatic carriage to acute gastroenteritis to pseudoappendicitis to a fatal and overwhelming sepsis, and vary with the host as well as with the infecting strain.[2,130] Several organ systems may be involved with *Y. enterocolitica* infection, either by directly or by immunologically mediated mechanisms, and the clinical manifestations can mimic other more common diseases. Patients may present with gastroenteritis, mesenteric adenitis, terminal ileitis, reactive oligoarthritis, erythema nodosum, exudative pharyngitis, or septicemia and coincident complications. Extra-gastrointestinal infections present as osteomyelitis, meningitis, and pulmonary and intra-abdominal abscesses. Other less frequently reported syndromes include carditis, ophthalmitis, glomerulonephritis, hepatitis, pancreatitis, and hemolytic anemia.

Acute, uncomplicated gastroenteritis is by far the most frequently encountered manifestation, particularly in children.[74,103] Acute *Yersinia* gastroenteritis is marked by diarrhea, abdominal pain, fever, and less frequently nausea and vomiting. This syndrome resembles acute infection with other enteric pathogens, and is not readily differentiated clinically, though abdominal pain occurring with *Yersinia* infection is often in the right lower quadrant, which is a diagnostic clue.

Symptoms of *Y. enterocolitica* enteritis typically persist for 1–3 weeks, longer than those of other enteric bacterial pathogens, and occasionally may last for several months.

Tonsillitis is not uncommon in acute yersiniosis, being reported by nearly 20% of patients in sporadic case series and 22% in one outbreak.[69,83131] *Y. enterocolitica* was isolated from throat cultures in 14 patients from this outbreak, illustrating the propensity of the organisms to infect lymphoid tissue such as the tonsils.[132] Since no other cause of acute bacterial diarrhea routinely produces pharyngitis, this symptom can be helpful in suspecting the diagnosis.

The syndromes of mesenteric adenitis, terminal ileitis, or both are more likely in older children and adults[131] (see Section 5.5). In these patients, diarrhea is less prominent, while findings of fever, right lower-quadrant pain, and leukocytosis often mimic those of acute appendicitis. The pseudoappendicitis syndrome has been reported in 3–15% of cases (see Section 5.1). While most cases are probably self-limited, the gut wall can be compromised and severe intestinal disease, small-bowel gangrene, and death have been reported.

A variety of extraintestinal manifestations may accompany enteric infection with *Y. enterocolitica*. Since intestinal symptoms may be mild or asymptomatic, many patients present with syndromes that mimic a host of other non-enteric diseases, and thus present a diagnostic challenge to the physician. The most common extraintestinal form of *Y. enterocolitica* infection is reactive arthritis. A non-suppurative arthritis has been reported most frequently in persons of northern European descent. In Scandinavia, 10–30% of adults with *Y. enterocolitica* infection develop inflammation of the knees, wrists, or ankles a few days to 1 month after the onset of diarrhea.[133] Cultures of synovial fluid cultures are generally negative. Symptoms usually resolve after 1–6 months but may become chronic in some patients.[134] The HLA B27 tissue type is a clearly demonstrated co-factor.[127] Reactive arthritis, sometimes accompanied by conjunctivitis and urethritis, as well as chronic progressive ankylosing spondylitis have been described in individuals with the HLA B27 antigen following *Y. enterocolitica* infection.[129,135]

Erythema nodosum occurs in up to 30% of Scandinavian cases, most of whom are women.[106] In the majority of cases, erythema nodosum resolves spontaneously within a month. This complication has not been linked to HLA type B27. The

causative agents of reactive arthritis and erythema nodosum belong to serogroups O:3 or O:9. These manifestations have been relatively rare in the United States, an observation that has been related to the geographic distribution of serogroups. However, an increase in cases with postinfectious manifestations of yersiniosis would not be unexpected, parallel to the emergence of serogroup O:3 in the United States (see Section 5.3).

Septicemia due to *Y. enterocolitica* is seen almost exclusively in infants or in individuals with underlying disease.[2] Those with cirrhosis and disorders of iron excess are particularly predisposed to infection and increased mortality. The cases of septicemia and shock that follow transfusion with packed red cells illustrate the severe nature of the infections in compromised recipients.[121] The blood donors for these cases are typically asymptomatic, which means that asymptomatic bacteremia among health adults occasionally occurs.

Transient carriage and excretion of both pathogenic and non-pathogenic *Y. enterocolitica* may occur following exposure to the bacterium. High rates of asymptomatic carriage have been reported in connection with outbreaks.[89] However, inapparent infection with *Y. enterocolitica* was detected in less than 1% of individuals in large surveys.[78] In patients with *Y. enterocolitica* enteritis, the organism may be excreted in low numbers in the stools for a long time after symptoms have resolved. In a study of Norwegian patients, convalescent carriage of *Y. enterocolitica* O:3 was detected in 47% of 57 patients.[131] In these persons, the organism was carried for a median of 40 days (range, 17–116 days).

Intestinal infection with *Y. enterocolitica* is usually self-limited and antimicrobial treatment is not routinely needed. Life-threatening sepsis, however, requires treatment. Antibiotic treatment has not been shown to shorten the duration of acute gastroenteritis due to *Y. enterocolitica*. In a retrospective case series from Norway, treatment was not associated with a decreased duration of illness (18 days versus 21 days).[131] No clinical benefit was demonstrated in a small prospective, placebo-controlled trial of trimethoprim–sulfamethoxazole in Canadian children.[136] However, the organism rapidly disappeared from the stools in both studies. There is also no evidence that early antimicrobial therapy reduces the frequency or severity of chronic sequelae.[137] Treatment of life-threatening infections with fluoroquinolones or third-generation cephalosporins has been associated with a decrease in mortality.[138]

Y. enterocolitica have been shown to be susceptible in vitro to aminoglycosides, chloramphenicol, tetracycline, trimethoprim–sulfamethoxazole, and third-generation cephalosporin antibiotics.[2,139,140] Most strains produce a β-lactamase, making them resistant to penicillin, ampicillin, and first-generation cephalosporins.[141] The recent emergence of reduced susceptibility to fluoroquinolones in *Y. enterocolitica* in southern Europe may herald coming challenges to treatment of life-threatening infections.[142]

8.2. Diagnosis

Diagnosis depends on isolating the organism from a clinical specimen, such as stool or blood. *Y. enterocolitica* can be easily isolated from sterile sites with routine bacterial culture methods The diagnosis of *Y. enterocolitica* gastroenteritis requires a degree of clinical suspicion and specific consideration in the clinical laboratory, so that selective isolation media are used for stool culture (see Section 3.4.1). Enterocolitis caused by *Y. enterocolitica* cannot easily be differentiated clinically from acute infections due to other enteric bacterial and viral pathogens.[2,131] However, *Y. enterocolitica* infection can present with distinguishing features that suggest the diagnosis. Tonsillitis and localized right lower-quadrant abdominal pain are diagnostic clues. A recent history of consumption of undercooked pork, drinking untreated water, or contact with pigs may suggest the diagnosis of yersiniosis (see Section 6). The diagnosis should also be considered when joint pains or erythema nodosum appears in persons with previous diarrheal illness, recurrent diarrhea, or abdominal pain.

Serological diagnosis can be useful in research studies to determine the role of *Y. enterocolitica* in postinfectious syndromes and other late manifestations (see Section 3.4.2). Several limitations of serodiagnosis make it problematic for use in clinical practice, including cross-reactions with other bacterial species and the prevalence of seropositive individuals in the healthy population.

9. Control and Prevention

9.1. General Concepts

Basic tenets of safe food production and preparation are critical to preventing these infections. Preventive measures that reduce contamination and improve hygiene during all stages of pig and pork processing are essential to reduce infection with serogroups O:3 and O:9. The organism may be difficult to control at the farm level. At slaughter, routine visual inspection will not detect the organism, as swine are healthy carriers of *Y. enterocolitica*, and bacteria from the oral cavity or intestinal contents may easily contaminate the carcasses and the environment in the slaughterhouse. Improved hygiene at critical control points is needed, with

special attention during: (1) circumanal incision and removal of the intestines; (2) excision of the tongue, pharynx, and particularly the tonsils which often harbor *Yersinia*; (3) meat inspection procedures that involve cutting into the mandibular lymph nodes; and (4) deboning of head meat.[34,45,117] Changes in slaughtering procedures, including technological improvements, may be required to reduce contamination during these activities. Routine treatment of raw pork and raw pork products with electron beam irradiation would greatly decrease infections arising from this route.[143]

Routine pasteurization of milk is another fundamental prevention measure for yersiniosis and many other infections. Milk-associated outbreaks of yersiniosis illustrate the need for careful sanitation measures to prevent contamination of milk after pasteurization, through contamination of the dairy environment and of empty containers before they are filled with milk. Particular care is needed in dairies that feed pigs leftover "swill" milk, as the transit of milk cans to and from the pigs can connect milk production and pig pens.[83,87]

Preventive and control measures should also focus on informing all people involved in production, procession, and final preparation of food about the importance of good hygienic practices. Strict hygiene is particularly necessary because *Y. enterocolitica* is able to propagate at temperatures approaching 0°C (Section 4).

The consumer can prevent infections through wise food choices and good kitchen hygiene. Infections can be prevented by not consuming raw unpasteurized milk, and raw or undercooked pork. Separating the two tasks of caring for an infant and simultaneously preparing raw pork intestines or other raw pork dishes can prevent illness in the infant.[88,114]

Y. enterocolitica is sensitive to chlorination, so proper treatment of drinking water should eliminate the risk of infection from this source.

Testing units of packed red cells for the presence of bacterial endotoxin, and limiting the shelf-life of packed red cells may be helpful in preventing transfusion-associated sepsis.[122]

9.2. Antibiotic and Chemotherapeutic Approaches to Prophylaxis

Antibiotic or chemotherapeutic approaches to prophylaxis are not indicated.

9.3. Immunization.

Vaccines against *Y. enterocolitica* infections have not been developed. The high frequency of immune-mediated complications of yersiniosis in humans has tempered enthusiasm for such research. Attenuated strains have been used as a means of delivering other antigens in experimental vaccine models.[144,145]

10. Unresolved Problems

Despite better understanding of the biological properties of the organism and its unique geographic and environmental distribution, many questions about the ecology, epidemiology, and pathogenicity of *Y. enterocolitica* remain unanswered. In many parts of the world, its importance is simply unknown. In New Zealand, a high incidence remains unexplained. To date, the important declines in incidence in Belgium and the United States suggest that control is certainly possible, though in the latter case the actual reasons for the decline are obscure. The development of standardized and approved laboratory methods is needed to allow optimal recovery of all pathogenic serogroups and to provide adequate differentiation between pathogenic and non-pathogenic variants. Standardized practical molecular subtyping methods that allow better differentiation within species and serogroup are needed to assist in public health surveillance, outbreak detection, and epidemiological investigation.

Although considerable progress has been made in our understanding of the routes of transmission and reservoirs for *Y. enterocolitica*, well-designed epidemiological investigations, particularly case-control studies, are needed to identify risk factors and determine their relative importance in endemic areas. Intervention studies are required to assess the efficacy of specific and nonspecific control and preventive measures to reduce colonization on the farm, contamination at the slaughterhouse, growth during storage, and spread in the kitchen. The strong association of the pathogenic strains with the swine reservoir suggests that specific interventions to immunize swine or otherwise reduce transmission among pigs may offer benefits to human health.

Great strides have been made in our understanding at the molecular level of the mechanisms by which *Y. enterocolitica* causes disease. However, further clarification of the role of the virulence determinants is needed. The evolutionary links between *Y. enterocolitica*, *Y. pestis*, and *Y. pseudotuberculosis* suggest that this genus may offer more general answers to the questions about how pathogens evolve, how they develop specific tissue tropisms, and how they become able to evade host immune response. All three share mammalian hosts, an ability to infect via the gastrointestinal tract, and cross-protective antigens. The historical puzzle of the apparent resistance of some medieval European populations to bubonic plague might be explained by cross-protection due to infections with other endemic *Yersinia*. The persisting clinical puzzles of human yersiniosis need to be unraveled,

including the role of iron in enhancing disease; the relationship of *Y. enterocolitica* to the immune system to produce a diversity of autoimmune phenomena; the potential benefit of early diagnosis and treatment; and the nature, efficacy, and duration of natural immunity.
